This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

INDEX.

Abdominal injuries and hemorrhages, J B Deaver, 193
Abdominal surgery, injured ureters in, 827
Report in, 71
Abdominal contusions, study of serious—T H Manly, 6
Abortion, modern treatment of, 580, 399, 146
Indications for induction of, 311
Absorption of pleuritic effusions after hypodermic puncture, 795
Abscess of the hand as a complication of gonorrhœa, 179
Accidental swallowing of a stomach-tube, 795
Accessory sinuses, surgery of, 175
Acetanilid as a surgical dressing, 650
Versus quinine to abort chills and fever; and acetanilid as a dusting powder—B H Brodnax, 444
Discussion, 468
Acne communis, treatment of, 317
Aconite in children's diseases, 489
Acromegaly, E L Bullard, 591
Acute catarrh in the middle ear of an epidemic character—S S Bishop, 589
Croupous pneumonia, J S Cain, 694
Discussion, 717
Diseases of childhood, 610
Tonsillitis, 609
Nephritis in the pneumonia of children, 813
From inunction with naphthol, 570
Supra-glottic œdemia without apparent cause, report of a case, 541
Bronchitis in children, W B Moore, 339
Inflammation of the middle ear, A H Buck, 158
Addiction to coal-tar derivatives, report of three cases, 133
Albuminuria in pregnancy as a cause of death of the fœtus, 685
Prognosis of, 899
Casts and bright's disease, 312
From anti-syphilitic treatment, 310
and nephritis in children, P LeGendre, 187
Albumin in urine, two easy and delicate tests for, 388
Alcohol in sick children, use of, 862
On the English military and civil population at home and abroad, effects of, 58
Alcoholism by strychnia nitrate, treatment of, 482
Alumnol, 867
Amylene hydrate, 611
Amenorrhœa, electricity in, 902, 239
Amputation of the entire upper extremity for sarcoma following rupture of the clavicle, W W Keen, 495
Through the knee-joint, De F Willard, 502
Anatomy of fallopian tubes, 76
Anal incontinence, 188
Anesthesia, new method of, 650
With death, and attempted extortion successfully resisted, a case of, 455
Anesthetics, 143
An ethical view of a medical question, M F De Hart, 185
Anemia, comparative value of different preparations of iron in, 275
Angio-sclerosis, C Cary, 401
Antitoxin, serum therapy in diphtheria, 284
Value in diphtheria, 640, 507
Manufacture of diphtheria, 636
Treatment of tetanus by, 641
Disagreeable action of the diphtheria, 274
Diphtheria treated by—T J Elterich, 568
Diphtheria treated with—W S Burleigh, 602
Anti-toxic treatment of the liver, 536
Anthropology, criminal, 255
Antipyretic, properties of a true, 32
Antipyrin as a vesical analgesic, 479
In laryngology and rhinology, 541
In large doses, use of, 643
Aphasia occurring during convalescence from typhoid fever, 939
Apomorphine, clinical uses of, 935
Apoplexy and thermogenesis, 680
In elderly persons, danger of, 615
Appendicitis, M Price, 476
Appendicitis, S C Lange, 226
Discussion, 242
Appendicitis, 328, 434, 612
When to operate in, 323
Its medical and surgical treatment, 107
Arch of the aorta, aneurism of the, R M Wigginton, 375
Are the uterine ends of the fallopian tubes ever pervious when the tubes contain pus? 759
Are milk sugar and galactose direct producers of glycogen? 570
Aristol in oral surgery, 831
In surgery, 508
In otorrhea and burns, 435
Army and Navy, 36, 112, 148, 256, 291, 327, 364, 436, 652, 687 724, 760, 832
Arthritism and sciatica, A Claus, 707
Articular rheumatism; ulcerative endocarditis; embolism C Cary, 883
Artificial anus, treatment of, 398
Ascities, strychnia as a curative agent in the treatment of, T J McKie, 409
Aseptic drainage tube, 646
Asphyxia, rythmical traction of the tongue in treatment of, 649
Asthmatic nose, 111
Atonic dyspepsia, 175
Atrophic gastritis, rapidly fatal, 75
Auditory functions, influence of fatigue on the, 830
Aural massage, 389
Auscultatory percussion and allied methods of physical diagnosis, A L Benedict, 581, 766
Auto-intoxication, J R Lemon, 295

Backward displacements of the uterus, Operative treatment of, 685
Bacillus, The, 35
Of the plague in China, 420
Bacterium coli commune and bacillus typhosus, differences between, 278
Bacteria, with special reference to bacilli of anthrax, tuberculosis and diphtheria, 279
Basedow's disease, Pathology of, 576
Beards, Blessedness of, 265
Belladonna plaster, Poisoning from, 237
Benign tumors of the larynx, Report of a case, D Roy, 405
Bicarbonate of soda, Use and misuse of, 34
Bicycle riding for women, 112, 320, 613, 614
Bichromate of potassium as a remedy in gastric affections, 215
Biting the nails, 147
Black eye, 397
Blood-letting in over-distention of the right heart, 543

BOOK REVIEWS.

Purdy, C, Practical Urinalysis and Urinary Diagnosis, 104
Reeves, J, A Handbook of Medical Microscopy, 105
Robinson, B, Landmarks in Gynecology, 105
Sayre, L E, Organic Materia Medica and Pharmacognosy, 104
Stedman, Thos L, Twentieth Century Practice of Medicine, 986
Thornton, E L, Dose Book and Manual of Prescription Writing, 679
Von Schienck, notzing, a, suggestive therapentics in poychoparhia sexualis
Warren, John Collins, Surgical Pathology and Therapeutics, 987
Wyllie, John, The Disorders of Speech, 670

Boiling water, Treatment of surgical tuberculosis, 208
Breakfast for chlorotic girls, 178, 648
Breech presentation, Sign of, 182
Brown-Sequard Method, 650
Butyric acid, Two kinds of bacteria that produce, 570
Burns, Antiseptic treatment of, 181, 436

Cæsarean section, Technique of, 819
Calculus impacted in the urethra with gangrene and rupture, T R Morton, 493
Removed by lithotomy, H R Wharton, 102
Discussion, 102
Cancer, Experiments on the inocubility of, 110
From man to animal, On transmissibility of, 901
Congenital and hereditary origin of, 416
A local disease, 180
Of the cervix uteri, Early diagnosis of, 144
New symptom of, 174
Of the breast, Operative procedure and statistics, 615
Cannabis indica, 569
Can ovarian dermoids be diagnosed, 325
Care of the ear during the course of exanthemata, 644
Care of navel in the new-born, 145
Carbolic acid, Local application in, 831
Poisoning, Changes in the respiratory organs in, 868
Carcinoma of the uterus, Complete hysterectomy for, 908
Castration on the female voice, Effects of, 645
Catarrhal inflammations, Operations for the relief of the middle ear, L Turnbull, 86
Catheterism of arteries, 165
Cataract, Three operations for extraction of: One artificial ripening of senile cataract, J M Ball, 342
Caution to anesthetizers, 471
Cerebral syphilis, Mental symptoms of, 576
Obscure case of, 575
Cerebral compression, Artificial respiration in, 795
Cerebral palsies of childhood, Report of six cases, T Diller, 519
Cerebral hemorrhage, Cause and premonitory symptoms of, 147
Cerebro spinal fluid, Lumbar puncture for the removal of, 540
Chest pains, 937
Chinese cruelty, 525
Children's diseases, New fight against, 100
Child crying in utero, 31
Chickenpox, Fatal case of uncomplicated, 467
Chlorine water in diphtheria, 573
Chloroform anesthesia, C Holtzclaw, 851
Discussion, 897
Brandy subcutaneously in, 418
Vinegar inhalations to relieve vomiting after, 795
During sleep, 683
Effects of, on the organism, 813
Chloroformization by the drop by drop method, 199
Chlorate of soda as a remedy, 274
Chlorosis, 361
Chloral hydrate in labor, 250
In hæmoptysis, 573
Cholera, Quinine as a remedy in, 469
Chordee, 218, 794
Chorea, Chloroform in the treatment of, 140
Fatal cases of, 433
Of pregnancy, 932
Rheumatic nature of, 76
Chronic constipation, Mechanical treatment of, 682
Heart disease, Dietetics of, 343
Inversion of the uterus treated by elastic pressure, 239
Kidney disease, Importance of early diagnosis in, 505
Purulent otitis media, Surgical treatment in, G E Seaman, 257
Recurring tetanus treated with thyroid extract, 215
Chronic tympanic vertigo, Its relief by surgical liberation of the stapes, C H Burnett, 162
Chrysarobin in chronic ringworm of the scalp, 216
Chyle cysts of the mesentery, 684
Circular insanity, 757
Circumcision, 218
Hygiene of, W F Glenn, 733
Discussion, 792
Circulation of the lymph in the small lymphatic trunks, 650
Cirrhotic rhinitis, Climatology in, C R Binder, 52
Clean thermometers, 553
Climatic causation of disease, I M Cline, 869
Clinical thermometer, J W Carhart, 119
Clothing of infants and children, 111
Cocaine, toxic properties of, 573
Cataphoresis in neuralgia, 867
Vomiting in pregnancy, 238
To prevent respiratory disturbances during chloroformizations, 831
Collapse from loss of blood, treatment of, 544
Common diseases mistaken or mistreated, 611
Common membranous sore throat, 628
Conduct of ordinary labor through external examinations solely, 110
Condyle fracture of the external, 219
Conception in the puerperium, 578
Congenital exfoliation of the skin, 538
Ptosis, 219
Conjunctivitis, boric acid in, 237
Constipation and its treatment, chronic, 217
Consumption, pretubercular and prebacillary stages of, O Manly, 149
Its prevention and treatment, T F Wood, 329
Prophylaxis of, 580
Contagious diseases, periods of isolation, 38
And infectious diseases, advertisement and isolation of, F Le Moyne, 819
Convergence to accommodation, relation of, H F Hansell, 820

CORRESPONDENCE

An open question, J E Free, 740
Benedict, A L, 200
Child crying in utero, G D Thomas, 304
Circumcision, Merrill Ricketts, 280
Diphtheria, A W Stimpson, 740
Foy G, 857
Inebriety, W F Mitchell, 19
Injection treatment of hernia, replies to inquiries, W H Walling, 94
Irrational treatment, F R Millard, 712
Leprosy, G W Clemson, 306
Morphinism in children, J B Mattison, 422
Pneumonia, cold in the treatment of, T J Mays, 525
Napoleon's favorite prescriptions, C B Williams, 789
Skunk as a source of rabies, F R Millard, 739
esuscitation of still-born infant by rhythmical tractions on the tongue, A Erskine, 525
Vaccination during the existence of a skin eruption, Advisability of, J A Cantrell, 422
Cough mixture, 396

SENSATION, PHYSIOLOGICAL AND PATHOLOGICAL.*

SHELBY MUMAUGH, M.D., LIMA, OHIO.

Man, God's most sublime marvel of understanding, is liberally endowed with inlets for stimuli to be conducted through the agency of molecular motion and vital force to his superior faculty of thinking. Impulses thus received stir up sensations which awaken our psychical operations. Perhaps a glance at their utility will exhibit the supreme importance of them. All of our acquaintance with the outside world, all of the accessible on a level with our capacities, all of the known this side of the end of human knowledge, rests upon sensation, physical, emotional (or may be latent, which when called into use goes by the name of reflex perception), for a basis. Its latitude is much broader than is usually supposed. To pass out of its circlet is to enter fairyland, a region of mists and shadows where even genius will grope her way in intellectual darkness striving to know the unknowable.

Between the alpha and omega of sensibility an ample compass is found for the broad range of thoughts' excursions. Imagination swings on its pivot and to be trustworthy must be consistent with its experiences—must point to the north, so to speak, the variation excepted. To go a step further, I believe as Condillac maintained, that the power of modifying conceptions itself is only a way of impressing the mind through the gateway of sensation. Certain it is that the organs bringing us in contact with the external world have much to do with the curious phenomena of the evolutions of the mental operations. Nerve currents, let us remember, play an important *rôle* in our psychic existence. Be it noted that sensations are not the property of corporeal systems, gentlemen, but are the mental responses of nervous action and belong to psychology. Without nerve fibers conveying impressions to and from the brain centers, this organ would be plunged deep into the arms of Morpheus with no functional existence. So, too, the in-carrying and out-carrying fibers, separate and apart from nerve cells, would be only neural strings without utility. It is by their mutual workings that man obtains this great functional activity of the most wonderful portion of his being—the nervous system. Like Chang and Eng, it is by their union that we always find them side by side.

Sensation dwells in the brain and depends upon it for existence. The end organs are merely instruments, for the eyes do not see, the ears do not hear, nor the fingers do not feel. Cut off the nerve fibers carrying messages from any organ to the brain and sensation of this organ is at an end thereafter. The histological construction and physiological action of the nerves conveying the impulses

*A paper read before the Northwestern Ohio Medical Association, December 13, 1894.

of sight, hearing, taste, touch and smell to the central nervous system do not differ in the smallest degree. The elements as elements are the same so far as now known. It is because the end organs of the optic, the auditory and the olfactory nerves differ that we have sight, hearing and smell respectively. Any centripetal nerve of special sense could as well carry in messages for any other sense organ as its own. Professor James has told us that "if we could splice the outer extremity of our optic nerves to our ears and that of our auditory nerves to our eyes, we should hear the lightning and see the thunder."

From the threshold or liminal intensity of excitation to that point beyond which additional stimulation fails to bring forth any noticeable augmentation in the mental impression, the effect hangs on the active power of that which arouses the vital energies and upon the degree of excitability. The ratio of the former to the latter varies with each sense organ. When the excitant is too intense the organ refuses to respond, but moderate use increases the acuteness of sensation. The mariner beholds a ship in the sensible horizon which is imperceptible to the landsman's sight. The microscopist and the astronomer learn to what extent one organ of sight will by practice surpass its fellow. It is instructive to civilization to know that the red man, by placing his ear to the earth's surface, can locate a moving herd of buffaloes miles distant or know the tread of a troop of cavalry. The accomplished musician has a capacity for receiving sounds and discriminating limits of pitch by far out of reach of the unskilled ear. He has a niceness of perception of harmonies and discords which is not found in the inexperienced artist. So the watchmaker acquires a nicety of touch of which the blacksmith forms no conception. And, too, the water-drinking Hindoo discovers a difference of savor in the waters of different springs which are alike insipid to the man who seldom drinks water. As a scientific study, the much-neglected sense of smell is receiving attention to-day, and D. McFarland Moore is of the opinion that in the near future the mind will be as much enchanted by a symposium of symphony in scents as by a symphony of sounds. Cut off smell and sight and the gustatory qualities will to a great extent go with them. After dining in a resplendent hall in the company of beautiful and accomplished ladies, in an atmosphere impregnated with fragrant odors, amid the harmony of soft and enchanting music, we are easily convinced that taste has been crowned and heightened by contributions from smell and sight. There is philosophy in compressing the alæ of the nose and closing the eyes when nauseating remedies are swallowed and in not doing so to obtain the deliciousness of delicacies.

Every individual educates and disciplines one organ of sense so that it becomes more perfect than the others. But, however, it is in those cases wherein a certain one has become permanently destroyed or never existed at all that we learn to how great a degree the others may be cultivated and improved so as to make good the deficiency. In fact, he who has a special sense shut is not the object of commiseration that he is usually held to be. Unaccountable feelings tell the blind that they are near a tree, high or low; in close proximity to a building, large or small; not far distant from a fence, open or solid; yea, a multitude of other things even more marvelous. The deaf, by giving careful attention to the movements of the lips and by observing numerous smaller motions of the features which are unnoticed by others, may be enabled to obtain a degree of knowledge, not of what is said, but of what the speaker means to say. The acuteness and accuracy of the sense of smell possessed by the oft-quoted Julia Brace, a blind and deaf mute, brought forth results beyod doubt surpassing the possibilities of the bloodhound's olfactory terminations.

In the rounding quarter of the eighteenth century it was considered the axiom of psychology that the senses should not be depended upon because of the mental deception of these five lenses by means of which we know or know not of the material world. In perceiving material objects the mind cannot be mistaken in any considerable degree, except by some natural or acquired defect in the bodily organs. How different—how very different it is in arranging the various relations and properties of objects and in that reflex action of the mind upon itself by means of which it is enabled to look back on its internal stored knowledge; for here imagination, attention, memory, as well as the corporeal organs, go to make up

the etiology of mental errors. It is only uttering a truth to say that these deviations from the direct course are not confined to the mentally deranged, but exist equally among men of the most healthy minds through mistaken judgments formed concerning the testimony of the witnesses of perception, yet here reason dissipates them. Many times reports of impressions are not correctly received.

The normal eye always exaggerates acute angles and underestimates obtuse ones. This is nicely shown by Zollner's lines. The phenomena of irradiation pictures to us dark objects smaller than light ones of the same size. You all, no doubt, have observed that the moon when in opposition appears smaller than when in conjunction, and that its crescent never seems to belong to the adjoining disk. Unwise would be the architect who would so design a column as to unsymmetrically divide an arch and thus bring out nature's illusion of discontinuity. It is because the visual effort required to see a horizontal line is not so great as that necessary to see a vertical line that the former looks shorter than the latter of same length. This optical illusion is taken advantage of by the mantua-maker, the artist, the paperhanger and the furnisher.

There is a strong tendency in man to see that which he desires to see. If this were not so, how could the fake medium succeed? It is indeed a very prolific source of error. We know how an interested witness not far distant, anxious to have the criminal detected, erred with reference to the identity of the suspected person, and how this same witness was quick to soon afterward positively identify another who showed no strong marks of resemblance to the former one. These mistakes are not infrequent and do not especially reflect upon the honest witness, but are what make criminal courts slow to take at face value the testimony of an interested party. They show that judgments concerning the testimony of sensation are not to be too much depended upon.

In every perceptive act the mental element is an important one. The mind often refers pain to the site formerly occupied by an amputated member. A fixed attention seldom fails to cause us to misjudge the location, maybe the direction, of sound. It is unnecessary to here dilate upon the illusions of movement experienced at the beach or at the railroad station. A former patient of mine maintained that he could perceive the rapid whirl of the globe upon its axis. A few similar cases have been recorded. Although such would be only the perception of an actuality, yet it could be due only to blotted brains.

Without doubt ideas have other sources beyond the end organs, because we gain knowledge of hunger, thirst and other bodily needs, of disease and of danger by means of organic and intellectual sensations, and experience enables us to locate them. Stimulation may occur, too, from mechanical jars of the central nervous organ and from changes in the quality and quantity of its blood supply. Before the youth becomes skillful in skating he realizes that stars may be seen subjectively, without any excitation being conveyed to the eye from without. The same effect takes place when we snuff some volatile salts. While this is all true, yet the plaintiff's claim at a trial of unusual interest in Germany that on a very dark night illumination from these sudden bursts of light of internal origin, caused by blow after blow upon the head, enabled him to see the face of his would-be assassin plainly, was refuted by all scientific evidence. These retinal flashes have not the power of imparting light to external objects. Subjective impressions frequently arise from the nervous apparatus being stimulated by internal somatic causes.

Knowing all this, does it seem strange to say that anatomy and physiology have prepared a fertile soil for pathology here as well as elsewhere? Pathological exaltation of organic action of the psychosensorial cortical centers may produce the highest degree of false perceptions characterized as hallucinations, while those changes or modifications by the sensorium of sensations actually arising from outward excitation are mistaken perceptions known as illusions. The former seldom occur except pathologically; the latter are common in all mental conditions. Certainly here is ample range for novel observations. From the beginning of mankind down to the present moment, both the former and the latter have held a great sway in the world's history. Their character is of the highest importance, furnishing a key to the singularities and eccentricities of the former individual

himself. He who hears a voice announcing his wealth or rank only may be quite harmless, but the one who receives commands to commit acts of violence toward himself or others requires careful watching or restraint.

Nothing could be more incorrect than the statement of an author in his new work that false perceptions of more than one sense are rarely present in the same individual. In fact, it is hardly the rule for a single sense alone to be thus affected. In sanity, those of sight are more frequent than any other sense; in insanity, those of hearing, because its center is in closer proximity to the intellectual region than that of sight. The relative position of the area affected is the pathological indicator directed to the extent of impairment of reason's faculties. Numerous are the cases where unhealthy states of the organs producing morbid sensation form the basis of false beliefs of the insane. Their genesis is sometimes due, too, to the blood supply being altered, thus affecting the brain molecules. Hallucinations may be seen with one eye or heard with one ear only. An animated dialogue is sometimes sustained with all the force of reality. Sometimes these sensations occurring entirely within the patient's own head are corrected by the testimony of others, but more often they are not. Here lies one of the greatest principles of treatment. A preponderance of certain health perceptions *can*, and if properly utilized *will*, contradict and overcome that which results from disease.

The sensorial organs may be so powerfully influenced by a dream as to leave the sensation of the impression on awakening, but they leave us rapidly, while in the insane they are not thus dissipated. Visual impressions are readily stored up by all of us. Were this not possible, Milton when blind could not have written a poem composed so largely of this imagery as "Paradise Lost;" nay, that branch of natural science calling for the most careful observation and the keenest eyesight could not have been mastered by Huber, who was blind from his seventeenth year. Behold a lunatic with his eyes open and his sight closed, or one with his ears open but his hearing shut, whose sensory ganglion was so forcibly struck from experiences before the special sense was closed that a shadow becomes a reality, and then you can realize that internal excitation is capable of reproducing sensations in consciousness without the agency of the end organs; for hallucinations of sight occur as readily in the blind, of hearing in the deaf, and so on, as when the end organs perform their work. To draw from my own experiences, a blind lunatic was firmly convinced that he could see gold nails on his fingers and beautiful flowers adorning the room; a deaf one that he received telephonic revelations from heaven inspiring him to convert the world. How else can such curious phenomena be explained except that sensations are laid up in memory as ideas reproducible in consciousness without the aid of the mind's special messengers? A linguist who is mentally deranged may hear voices in different languages.

In health and in disease the central nervous organ is excited from within almost as frequently as from without. From the fact that hallucinations of sight take place in the blind and when the optic nerve is atrophied, we learn that the retina is not the seat of false visual images as it is of mistaken and perverted ones; therefore the pathological character of illusions and hallucinations differs. Closing the eyes will of course dispel the former, but seldom the latter. To not believe false beliefs is to repudiate the testimony of the witnesses of perception, for many times they are real sensations forming channels through which reason flows. Until the basis is corrected the chain of reasoning cannot be changed by legerdemain or otherwise, so that trick and artifice, once so popular in the treatment, have been relegated into disuse. Even objective reality often fails in influencing perverted or false sensation. Until the foundation is made aright the reason will remain unchanged.

Not only are painful sensations common among the insane, but also tactile hallucinations and even delusions of physical transformation are not uncommon. One whom I vividly recall fancied that he had become petrified; another that his body had been metamorphosed into that of a wolf; and still another that all his bones had changed into flesh. Morbid sensation was surely responsible for the false idea in each case. Many are the fantastic transformations which objects out of the brain may undergo. Sensations which cause the sufferer to declare that insects are crawling on the skin or destroying

some vital organ sometimes occur. These peculiar conditions causing discomfort in this or that part of the body are often the outcome of lesion of the organ. When the morbid feeling subsides the morbid thought usually vanishes.

Inasmuch as these sensations are strange, mysterious and unaccountable, patients likewise fly to the same sources for the causes thereof. The fashion of the age has much to do with the causes assigned for the sad state by those affected. In times gone by lunar vicissitudes, eclipses, comets, devils and witches were to blame; so said the people—those affected and those not affected. At the present day we all know what morbid sensation has to do with them, yet the afflicted seem to think they are due to electricity, hypnotism, etc. Pathological sensation is always shaped by the stores of knowledge, the education and the experiences of the individual, therefore continually keeps pace with the advance of the times.

By being familiar with the importance and significance of morbid sensation, the family practitioner would frequently be enabled to ward off impending insanity at its onset. Just at this time, when man is as near sanity as insanity, the senses begin to wander and morbidly deceive because of an incredible acuteness or intenseness in sensation, and great ends may be reached. Just at this time most can be accomplished by the agents of materia medica and by moral suasion exercised by man over man. The therapeutical treatment of these conditions is an extensive and important subject—one which cannot be dealt with here. Its area is found to be spread over a large portion of the area of materia medica. To lay down a broad rule, medicines have no special action of their own in these affections—they do not operate peculiar to the peculiarities, but are called for in general to restore corporeal derangement and are to be used under the same conditions and for the same purposes as in general medicine. They cannot be taken up separately in this connection, as this subject alone would require a volume for its successful exposition; therefore will be passed by as a whole.

Allow me to now swing to the science of the human mind—to its physiology, where the effects of mental attention on the bodily organs at once appear. An intimate inter-relation surely obtains between mind and sensation. The latter cannot be studied apart from the former, amid which it invariably takes place. On the other hand, all functions of the mind are followed by sensibility of some sort or other. Thus you see a reciprocal relation exists—each is affected and influenced by the other. Morbid states of sensibility are concrete diseases affecting the mental operations with coexistent disorder of the sense organs. Without touching upon any abstruse points of metaphysical inquiry, physiological experiments have proved that the activity of a region, organ or part depends greatly upon the blood supply to it. It is in conformity with a general law that the effects of habitual repetition of stimulated attention to particular organs or parts of the body alters the supply of blood to them, creates unusual sensations in them and in time deranges their functional state. There is no difficulty in generating local sensations by merely seeking for them and expecting their occurrence. It is as much the duty of our profession to remove distress occasioned by subjective painful sensation as to cure real morbid states of organic structure. This may be accomplished by passing beyond materia medica and utilizing mental agents on the bodily functions, for they cannot be safely disregarded in the preservation or restoration of health.

It is too true that we prefer to see our fellow-man in distress and misery rather than to cure him of his affection except by means of powder, potion or pill. We are moving slowly but surely to the patient's mind itself for the basis of treatment of morbid nervous troubles occasioning pathological sensation. Mental philosophy itself calls for the cultivation of the reflection, the training of the observation and the governing of the thoughts in their treatment. While but little advantage could ever come from attempting to prove the falsity of morbid sensation in any form, yet irreparable damage results from admitting it to be true. In the charming pages of quaint old Burton is found the somewhat remarkable statement that "if they say they have swallowed frogs or a snake, by all means grant it and tell them you can easily cure it." The fallacy of dealing with pathological feelings by such procedure was completely exposed long ago.

It is a hard fact to admit, but neverthe-

less true, that the charlatan can sometimes actually cure hypochondriasis, neurasthenia, hydrophobia, hysteria, some forms of incipient insanity and other real diseases after the scientific physician has called into use his most potent remedies. Now if the empiric can really effect such cures, what could not be accomplished if the medical profession would give mental agents due attention? Certainly, wonders indeed. And, too, without resorting to their nefarious methods. As the wise man of old said, "*Fas est ab hoste doceri.*"

The time is comiug when every medical college will have a chair of psychology, and the ways and means of laying out the road to health for the patient's mind will open a scientific field of broad dimensions. The time is coming when treatment of morbid states of the end organs of sense through the medium of the inner man will rest upon organized knowledge for support. The time is coming when the scientific solution of the mysterious relations of mind to the complex and subtle organization of matter will give medicine its highest character as a science. And then our profession will find it unphilosophical to attempt to separate mind and matter in practice, so intimately are they associated; indeed, both being parts of one great united system of reciprocal action and mutual contribution. May God speed the advent!

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., New York.

[CONTINUED FROM PAGE 901.]

REPORT OF CASES—*continued.*

Case XIV.—Contusion of abdomen. History: Patient male; aged thirty-six; single; admitted to hospital May 23, 1894. Diagnosis: Contusion of abdomen, rupture of intestine, internal hemorrhage and dislocation of right shoulder.

The subject of this history was a hearty, muscular man of about the average height and weighed about 225 pounds.

In his early boyhood he met with an accident by which he lost his right leg, and as a substitute he wore an artificial member.

About two hours before he was brought to hospital he started out for a drive with a powerful but badly broken colt. While driving by a trolley electric car the horse was startled by the sound of the gong and undertook to run away, but his muscular driver was too much for him and held him in. He then reared, plunged and tipped the carriage over, but he was manfully held in. He now became furious and commenced to violently kick, striking his unfortunate driver with terrible force, first dislocating his left shoulder and then sinking his hoofs into his abdominal walls. The driver quickly went down under this battering and let the reins fall. Succor was promptly at hand and an ambulance soon arrived. I saw him immediately after admission to the hospital. He was then in great distress, complaining mostly of the abdomen. The first thing done after he was freely stimulated was to reduce the dislocation. His abdominal pain was most agonizing, and though morphine was administered in very large and repeated doses and hot stupes were applied over the abdomen, relief was not complete. His state of shock was most profound. The skin was marble-white and gave free issue to a cold perspiration. The hands and feet were rather cool. The features were pinched, the eyes sunken and lips bloodless. His urine drawn away with the catheter was normal and bloodless. Over the abdomen there was no trace of injury, neither abrasion nor ecchymosis. But it was everywhere painful, and though both pupils were contracted from full opium narcosis, still he groaned with pain. Tympanites was well marked, the distention being so great as to interfere with the movements of the diaphragm. As the abdomen was so deeply covered with fat, it

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

was quite impossible to locate any of the organs or determine any local lesion. With his legs drawn up and the chest raised he was most comfortable. Treatment was actively instituted for the dual purpose of annulling pain and overcoming the effects of shock, and next with a view of arresting peristalsis and securing quiet to the injured viscera. From the marked anæmia it was evident that some important vascular organ had been lacerated and that there was internal hemorrhage. Of intestinal rupture there could be scarcely a doubt. The extreme and sudden tympanites decided this; besides, the agonizing, incoercible pain was quite conclusive proof. The pain of intestinal perforation may be distinguished by its quality, as it has been my fortune to verify in laparotomies on the living and on post-mortem examination on those who have died from intestinal lesions. In two hours this man received two grains of morphine hypodermically, besides nearly a pint of brandy, without wholly subduing the pain. After about three hours the pain came and went alternately in spasms, probably synchronously with the peristaltic wave or contraction of the abdominal muscles. His strength gave way rapidly, the pulse steadily weakening and the extremities colder. At 9 P.M. he died, just six hours after entrance. About half an hour before the end came the dying man informed his mother that "the pain was gone and he now hoped to have a sleep."

In this case an autopsy was denied us.

A kick from a horse, delivered squarely and with full force, is often terrible in its consequences. The skull gives way like an egg-shell under it. The thoracic cage, with its pneumatic buffers inside, will sustain it better than any other part of the trunk. The spine is remarkably resistant too, for among more than a hundred cases of spinal traumatisms which have come under my care I have never seen one in which the cord was implicated in which the injury was caused by the kick of a horse. But the abdomen is especially vulnerant to this quality of force, and statistics show that many of the mortal types of abdominal contusion succeed from such injuries. This man's general condition was so desperate from the time he entered as not to permit us for a moment to consider an exploratory laparotomy. The probabilities are that had we undertaken one, like the previous case it would have ended mortally before we could return him to his bed. As to the propriety of experimentation in the way of inflating the intestine through the rectum with air or gas for the purpose of verifying diagnosis, it does not seem clear what can be gained by forcing fæcal matter out through a perforation into the peritoneal cavity, or even should there be any reliance placed on the test at all, of what does it avail when to do an operation is to kill one's patient?

CASE XV.—Contusion of abdomen (compressive). History: Patient male; aged twenty-seven; single; admitted to hospital June 2, 1894. Diagnosis: Contusion of abdomen with fracture of last two floating ribs close to junction with vertebral column.

On the morning of the above date patient, who was the driver of an ice-wagon, was injured by a collision accident. He was seated in front, having on a little more than two tons' weight of ice, drawn by two horses, when another passing heavy team, moving in an opposite direction, collided with the front wheel of the left side of his wagon. The opposing vehicles came together with such suddenness and clash that he was thrown out on the right side, striking the ground on his chest. Immediately before he could extricate himself he was caught and run over by the front wheel of his loaded wagon, it passing obliquely across the wings of the scapular. In the frantic efforts of eye-witnesses to stop the team the frightened horses, instead of going ahead, suddenly turned, this movement bringing the hind wheel in such a position that it crossed the body just over the iliac and lumbar segment of the spine.

After being doubly crushed by this tremendous weight it was thought that he surely had been killed. He was in such terrible shock that the physician who was first called pronounced the case as quite hopeless, as he breathed only in gasps and was quite pulseless. After two hours' interval he had partly revived and an ambulance was called, when he was taken to the hospital.

Soon after he entered I saw him. He was yet in great shock, though coherent. He complained of severe pain all over the abdomen and over the hypochondriac region of the abdomen. He had twice vomited a bloody fluid, and urine drawn away

was blood-tinged. The two lower floating ribs on the right side were found fractured close to their vertebral attachment. There was free hemorrhage into the left pleural cavity which spread far into the tissues over the seat of fracture. The whole abdominal areas were extremely sensitive, particularly over the liver, and the symptoms of free intraperitoneal hemorrhage were quite unequivocal. The intestine had evidently escaped in this violently flattening-out process. There was a distinct mark of discoloration and abrasion where the front wheel passed, but none over the abdomen. There was no paralysis, though he complained loudly of severe abdominal pain. Morphine and topical applications had to be vigorously applied. Reaction was gradual and fairly reëstablished, when pleurisy and peritonitis set in. Constipation, abdominal distention and exquisite pain announced the latter, and diminution of respiratory murmur, with acute pleuritic pain and the friction rub, determined the former. Opium, stimulants, frequent enemata, and with the free employment of mercurial inunction over the integuments investing the thoracic and abdominal viscera, seemed to maintain him and keep inflammation under control. His youth and fine constitution contributed their share in holding him up until the storm of reactionary disturbances had blown over and function had become reëstablished.

During the second week he was in the hospital his integuments became stained by a moderate tinge of an icteric hue, the hepatic area was very sensitive, and other associate symptoms pointed to an attack of traumatic hepatitis. His recovery was gradual, but steady, and after the third week he was able to sit up.

July 9th he left the hospital quite recovered, his strength and appetite restored and all his functions restored.

The features of special interest in the above remarkable case were, first, those referable to the spine. We had here demonstrated the fact that when the lumbar spine is crushed by compressive force the primary effects of it are manifest, first, through the abdominal organs which lie loosely anterior to it, which suffer through transmission, the inclosed *corda equina* always escaping, except when the force is applied with great impetus and is concentrated or when the underlying organs are mortally damaged. Secondly, the costal fracture. There can be no doubt but the elastic resilient ribs offered great resistance to the force brought to bear on the back, and so diffused it as to greatly diminish the immediate effect of its impact. Thirdly, the rapid resorption of the pleural and peritoneal hemorrhagic effusions.

The projecting pneumatic buffers which over-roof the liver and the stomach suffer their outer costal walls to be fractured in different places and scatter concentrated force in various directions when force is applied; the lung itself being lacerated before the abdominal organs are involved.

CASE XVI.—Contusion of abdomen (compressive). History: Patient aged thirty-two; married; brakeman; admitted to Harlem Hospital January 19, 1894. Diagnosis: Laceration of the liver with rupture of the stomach and urinary bladder.

At about dusk on the evening of above date patient, who was a new hand at railroad work, was assisting in making up a train in the New Haven yards. He stood on one track waiting for a train to move out on another. In the midst of the noise inseparable with moving trains in a freight-yard, and while he was watching another train, a car being pushed down the track that he was on by an engine, before he saw it hit him a violent blow on the abdomen and knocked him outside the rails.

He lay where he fell for nearly an hour before he was missed. When found he was unable to speak. He was brought into the freight-house and remedies were vigorously applied by attending physician. After three hours he rallied and was sent in to hospital. Was now conscious. He could speak in a feeble whisper and said he was dying.

At this time the hands and feet were chilled by that icy damp cold of death. No radial pulse. The sunken eyes, the collapsed nares and blanched skin clearly indicated that the end was near and that some large blood-trunk had been torn open. He died a few hours after entrance.

Post-mortem examination thirty hours after death. No discoloration of integument. Right rectus abdominalis ruptured through upper third. Peritoneal cavity full of blood and aliment; the center of the convex surface of the right lobe of the liver was the seat of a stellate laceration which opened widely the hepatic sinuses. Rup-

ture of the portal vein about half an inch above the confluence of its tributaries.

A rent about four inches long involved the posterior wall of the stomach, extending through all its tunics.

Another laceration was found running transversely across the fundus of the bladder two and one-half inches long. No bones were fractured.

This case was one which so fully demonstrates the destructive force which so generally attends grave railroad injuries. When a limb is mangled by a railroad smash we almost invariably find the tissues terribly mutilated above and below the point of injury, the integument often being devitalized far above it. And likewise in abdominal cases the extent of destruction is terrible. Two other cases of railroad injuries of the abdomen have come under my observation, but in both the moribund state had set in before the ambulance arrived to take them to the hospital.

CASE XVII.—Contusion of the abdomen, resulting in appendicitis; general peritonitis. History: Male, aged fourteen; admitted to hospital June 26, 1894. Diagnosis: Traumatic peritonitis following contusion of the abdomen.

Patient stated that ten days before, while standing on the rear of a vender's wagon filling a pail with potatoes, his horse suddenly started and he was thrown out, striking his body with great force against the upper rim of the wheel. He was somewhat dazed for a while, but was able to get up, having a moderate spasmodic pain in the right iliac fossa. He was able to keep at his work for three days; by the fourth the pain became so intense that he was quite unable to rise. Now medical aid was called and moderate purgatives prescribed. For three days he remained in bed without making any improvement. On the tenth day after injury he was sent to Harlem Hospital.

Condition on admission was very weak. Moderate vomiting; temperature, 104°; pulse, 118; respiration, 27; abdomen tumefied, exceedingly tender everywhere and suffering constant pain. No marks nor abrasions on abdominal walls. Free inunction of mercury over entire abdominal area; opium given freely; moderate enemata.

The following day much improved; vomiting ceased and thirst greatly diminished. Temperature, 99°; pulse, 94; respiration, 22.

June 28th. No pain in abdomen. Sitting up He was hungry. Temperature, 99°; pulse, 88; respiration, 21.

As he was now apparently convalescent and only needed a few days more of rest, and as our service was crowded he was transferred to Bellevue Hospital.

From the hospital records we learned that shortly after his arrival there serious abdominal symptoms developed. Dr. J. D. Bryant, into whose service he was sent, made incision into the median line and evacuated a large quantity of pus; irrigated, etc. The boy died the next morning. On autopsy the appendix was found perforated and gangrenous. This was a case evidently in which the starting-point of the trouble was in the abdominal contusion, which probably crushed the appendix. It has been a mooted question whether a traumatism can be regarded as an etiological factor in appendicitis. It is my firm conviction that it is.

This caudal appendage is indeed vermicular not only in contour, but also in its freaks and excursions. It may grope down into a hernial sac. It commonly lies down over the pelvic brim, its tip resting in the pelvic cavity. It often turns on itself and finds lodgment under the cæcum. Its tip has been found adherent to the liver, and in an abscess which was lately opened by myself to the right of and on a line with the umbilicus it was found fixed there.

When it hangs suspended over the pelvic brim it is particularly exposed to damage from such compression or contusion as will press it up against this sharp ridge. Possibly it occupied some such position in this case, though the autopsy notes do not state it.

In the parturient woman it can scarcely escape injury in this situation when the fœtal head becomes impacted.

Very recently a case came under my care in which delivery had been attended with great difficulty. From time of confinement the patient constantly complained of severe pain in her back and right loin. Four weeks after confinement a swelling appeared above the crest of the right ilium posteriorly. At this time she had well-marked symptoms of local peritonitis with general septic infection. I made a deep

dissection over the mass and came down on a cavity filled with gas, fæcal matter and pus. After free drainage a good recovery succeeded.

This was clearly a case of traumatic appendicitis originating at accouchement.

In this boy we saw well illustrated the insidious manner in which serious consecutive lesions may follow after an apparently insignificant abdominal injury at the outset.

Case XVIII.—Abdominal contusion; the body falling. History: Patient a male; aged forty-four; engineer; admitted July 17, 1894. Diagnosis: Contusion of the abdomen with lacerated kidney.

On the above date patient fell from the motor-house of a drawbridge to the driveway below, a distance of about twenty feet. In his descent his right side came with great force against a rail upright. In connection with the abdominal injury he sustained a Pott's fracture of the right leg. He was immediately transported to the hospital. On admission he was in shock and suffering great pain in his right side over the lumbar region.

He was seen by me the following morning. At this time he was free from pain unless he attempted to move. On the right side as far back as the spine, up over the four lower ribs, down over the crest of the ilium and for a considerable distance inward, there was a large discolored tumefied area. This imparted a sense of fluctuation and was everywhere flat on percussion. From the time he entered he complained of an intense desire to urinate. On the passage of the catheter the bladder was found to be distended with blood. This was more or less clotted, of a bright red color and mixed with urine.

The bladder was irrigated with a warm solution of boracic acid and local dressings applied over the seat of injury.

On the third day after admission he had a chill, after which symptoms of cystitis and a localized peritonitis over the seat of injury and the hypogastrium were well marked. From this time the passage of the catheter was so painful that cocaine solutions had to be employed each time to blunt sensation.

Symptoms of urethral fever gradually set in, sleep was irregular and he became feverish and fretful. The bowels acted well and he took freely of fluid nourishment.

After the first week he steadily failed in strength and symptoms of toxæmia steadily increased. After the end of the third week he drifted into a somnolent condition, in the mean time the urine continuing very bloody. He finally succumbed on the 10th of August from a mixed condition of exsanguination and urethral fever.

In this case we had an illustration of those urinary sequelæ which may follow when the kidney has sustained an extensive laceration or disorganization from violence, and such constitutional disturbances follow as may imperil life.

It was clearly evident from the physical examination that the kidney had been extensively lacerated and there was a large sanguinary and urinary leakage into the retroperitoneal tissues. The most serious complication, however, came from urethral and vesical irritation and fever.

For some cause, not by any means clear to me, in certain cases the most disastrous consequences follow the passage of the catheter into the bladder. To say that it is due to septic infection proves nothing. My own experience inclines me to dispute this view, for the reason that I have seen it develop when every antiseptic precaution was taken. On the contrary, we see those who catheterize themselves with stiff, solid old instruments as a daily practice for years with impunity, as far as infection goes. Hæmaturia in this case was so excessive and persistent as to produce a most pronounced anæmia, which so exhausted the general system as to reduce its resisting power to the effects of trauma.

Death in this instance was primarily and ultimately produced by renal and urethral trauma alone. The peritoneal inflammation remained purely local, as it did not spread beyond the parietal investment anterior to the kidney.

Case XIX.—Abdominal contusion. History: H. H., aged thirty; single; male; admitted to hospital August 4, 1894. Diagnosis: Contusion of abdomen, rupture of internal organs, internal hemorrhage and shock.

Patient was employed in excavating rock. On the day of injury he was struck with great force by a falling bowlder, which struck him over the umbilicus, and knocked him down.

It was at first supposed that he was

killed outright, but he soon recovered consciousness and the circulation became reëstablished; was immediately brought to the hospital.

On admission the extremities were cold and pulse was gone at the wrists; complained of great abdominal pain over the hypogastrium.

Evidence of free internal hemorrhage with rupture of the liver and deep vessels. No trace of injury over the integument investing the abdomen. No paralysis of extremities, but fæces and urine flow away involuntarily.

Stimulation and artificial heat made no impression, and he died one hour after admission, deep collapse continuing to the end.

In the foregoing case death ensued from internal hemorrhage, probably either from laceration of the liver or a rent through the vena cava.

In this case possibly we might suppose that an immediate abdominal section should have been performed, with a view of attempting to suppress hemorrhage, but when we come to practically deal with such a condition as was here presented, we appreciate how fallacious theorizing often is. Our man was in practically a moribund state when he was brought in. And, unhappily, often when we can detect the source of hemorrhage we are powerless to check it before alarming symptoms set in, that in order to avoid killing our patient we must desist.

Case XX.—Contusion of abdomen (percussive). History: Patient aged forty-two; married; laborer; admitted to hospital August 12, 1894. Diagnosis: Abdominal contusion with fracture of eighth and ninth ribs.

Patient, a carter, had unharnessed his horses and was about to put them into the stall, when another horse passing raised his hind legs suddenly and gave his driver two violent kicks with both hoofs, knocking him down.

For some minutes he was unable to raise himself. When he was brought into hospital was in great pain over the chest at the site of injury and over the umbilicus.

The eighth and ninth ribs were fractured near their chondral articulations and there was evidence of free hemorrhage into the pleural cavity. There were marks of contusion over the broken ribs, but none over the abdomen.

Complained of a steady severe pain in the epigastrium. Abdomen everywhere very sensitive. General condition fairly good. The chest was braced by adhesive straps and bandages. With hot aromatic drinks and warm stupes over abdomen pain was moderated and he rested quietly. This case progressed steadily toward recovery, and he left the hospital quite well after a two weeks' sojourn.

In this case the brunt of force was first received and neutralized by the costal walls of the thorax. The contusion of the abdomen was probably caused by the sudden kick, which probably, besides bruising the muscles and concussing the viscera, did little harm. The case properly belonged to what might be regarded as a parietal or extrinsic injury of the anterior boundary of the trunk.

Case XXI. — Abdominal contusion (compressive). History: Patient a driver; twenty-seven years of age; single; male; admitted to hospital August 27, 1894. Diagnosis: Laceration and contusion of the liver with severe compression of the stomach.

On the morning of this date, immediately after breakfast, a young man having loaded his wagon for market, and his horse being harnessed and standing yet in a covered shed, when he went behind the wagon for something the horse suddenly was startled and forcibly backed the wagon against the driver, who could not extricate himself. He was crushed with great force directly across the abdomen above the umbilicus, being caught between the back part of the wagon and the wall of the building. Immediately after backing the animal made a plunge forward, when the injured man fell to the ground in a helpless state. Stimulants were given him and he was sent at once to the Harlem Hospital. On entrance he was in great shock; extremities cool and he was almost pulseless. Was promptly placed in bed and restoratives given. Urine was drawn with the catheter. His state was so precarious during the first twenty-four hours that no attempt was made to do anything more than make a superficial examination. By this no sign of injury could be detected by any discoloration of integument over the abdomen. But he was very sensitive to pressure over the abdomen and liver and all the superior areas of the abdomen. During the first day in the

hospital he suffered from intense abdominal pain and hæmatemesis. The abdomen was hard and flattened through contraction of the muscles. Physical examination revealed the presence of fluid in the peritoneal cavity, which, judging from the sudden and extreme anæmia he suffered from, no doubt was a sanguinous accumulation. Moderate jaundice appeared on the third day, but the urine had a slight and evanescent bile tinge. Constipation persisted for the first six days. Traumatic peritonitis was unequivocal, though it was chiefly parietal and at no time took on serious symptoms. His recovery was gradual, and after six weeks in the hospital he left for home fairly restored, still, however, rather weak.

It was interesting to note here that after the fourth day a broad annular belt of discoloration appeared above the umbilicus which had not quite disappeared when he left the hospital.

This was an instance of typical hepatic traumatism in which the gall-bladder escaped. Though breakfast had been eaten less than half an hour and the stomach was distended with food, it escaped rupture; still from the free vomiting of blood which followed there was no question of extensive laceration of the internal glandular and muscular layers. The liver was damaged by being crushed between the arched anterior shafts of the five lower ribs and the spine. The liver, in common with other solid viscera of the abdomen, suffers trauma with singular tolerance and in the healthy, vigorous subject possesses great recuperative energy. This was well illustrated here.

The development of the line of discoloration on the fourth day was a phenomenon which we commonly witness over those soft parts which are not supported by an osseous understructure of resistance.

Discoloration of the integument depends primarily on effusion of blood from the capillaries and consecutively on the chemical changes and evolution of gases. These depend on the circulation; therefore why when reaction does not set in these phenomena are absent.

COMMUNICATIONS.

WISDOM AT THE BEDSIDE—FACTS AT THE POST MORTEM.

JOHN J. TAYLOR, M.D., Streator, Ill.

In the month of June I was called in consultation to see a gentleman lying ill in St. Mary's Hospital. The man was apparently about fifty years of age. His face was flushed as with hectic, rather spare and slightly pinched and bore an anxious expression. The eyes and skin were icteric. His respiration was about 40 and the pulse varied from 125 to 140. Temperature 102° to 103° F.; the tongue was dry, rough, heavily coated yellowish to dark brown, and decidedly pointed and tremulous when protruded. Bowels constipated; urine scanty and of very dark color. Occasional vomitings; loss of appetite. Skin dry and husky. Mind clear. The body was very thin. The bedding thrown back and his chest bared showed quiverings of the tissues at the point of the sternum from the heart's action. The left ribs did not rise and fall; the intercostal spaces were obliterated and the left side seemed somewhat larger than the right, and by measurement proved to be so, though by only about one inch. Below and extending above the lower edge of the eighth rib, about half-way between the sternum and vertebræ, was seen a white line or cicatrix about a half-inch long, alleged to have been produced a number of days previously. Percussion revealed a normal condition of the right lung, but on the left from the third rib down there was a high, dead sound characteristic of a solid body, such as emitted by percussion over the liver. The stethoscope detected a high-sounding respiration, but otherwise natural condition of the right side, while on the left side above the third rib râles and sibilant bronchial respiration were

noticed. Below the third rib no sound was detected save the faint, muffled beating of the heart.

My diagnosis was that the left pleural cavity was filled with a fluid, probably sanguino-purulent in character, the result of the wound at the site of the cicatrix mentioned. From the time of the alleged injury three weeks previously the patient had fever constantly. Notwithstanding antipyretics had been sedulously given, only temporary benefit was derived from their use. Septicemia was the cause of the fever. My advice was to tap the chest and draw off the offending matter; the first and greatest chance to save the patient. In any event the prognosis was unfavorable.

When paracentesis thoracis was advised the friends and patient were not ready for so radical a measure. I did not again see the man for a week. In the mean time another consultation was held, and the consulting surgeon assured the friends that there was no fluid in the cavity, or if there was it was only a small amount, which would be absorbed when the traumatic pneumonia terminated. As the patient grew worse I was recalled.

The patient was now less inclined to eat, could not rest and had lost strength. The same general symptoms were present. Along the left chest walls, particularly over the pectoral muscle, there was considerable infiltration-edema; the back of the left hand was also swollen. The patient now insisted and the friends were ready for an operation. "Anything to give me relief," he said. So the time was set for that afternoon. The Sisters, ever willing and efficient, had all in readiness at the appointed hour. The clothing removed, an oilcloth was placed beneath the patient; he was washed with hot water and soap, followed by sponging of the chest wall with sterilized water. An incision was made through the skin a fraction of an inch from the cicatrix mentioned and just above the ninth rib, and the fine Allen aspirator trocar was thrust through the intercostal muscle close to the upper edge of the ninth rib into the pleural cavity for two inches. The needle was withdrawn and a very dark sanguino-purulent fluid escaped into a two-quart basin, which was filled three times, six quarts having been drawn off. When the fluid failed to run it was pumped out with the aspirator. The cavity was thoroughly washed out with sterilized water until the water came away perfectly clear.

The patient was somewhat fatigued, but expressed himself greatly relieved. The distress for breath seemed almost gone; the heart's action was improved. The patient slept several hours that night, the first sleep in a long time. His appetite was slightly improved for a day or two; the body temperature was somewhat diminished; the pulse slowed; vomiting ceased. But the improvement was ephemeral and deceptive, for in a few days it was evident that he was losing ground. The day following the operation, in different parts of the chest could be heard coarse, moist râles with sibilant bronchial respiration.

Something like a week passed, and it was deemed best to repeat the tapping. This was done, with thorough washing out of the pleural cavity after the removal of a quart of purulent fluid. The respirations continued at from 35 to 45. Emaciation progressed. He became more icteric and, save the cough and lack of expectoration, he looked and acted like a man suffering from consumption. I saw the patient perhaps a half dozen times and used the stethoscope and percussion each time. I was able to hear a respiratory murmur, although weak, over different portions of the left chest, the râles and sibilant respiration being present in every examination. Three days before he died I saw him, and the physical signs showed some reaccumulation of fluid. He was very much exhausted. A whizzing sound, similar to that in emphysema, was heard. The tongue was dry as a chip and very dark. Urine very scanty and dark. Pulse feeble. In fact, the man was gradually passing from life into the shadow of death.

Post Mortem: On invitation from the attending physician to be present at the autopsy, I learned that the coroner wanted a Democrat to hold the post mortem, saying: "This is a Democratic administration and we Democrats must have all there is in it." So as a looker-on the following conditions were observed: Complete rigor mortis; the usual incisions in the skin made and the costal cartilages separated, the manubrium and cartilages were tilted up over the face and the chest cavity was in full view; the left pleural cavity con-

tained a large quantity of purulent fluid which was poured out by tipping the body on to its side and the removal completed with a sponge; the pleura, at two points, was entirely destroyed, exposing the roughened ribs; the pathological lung measured seven inches long, four inches wide and an inch in thickness—estimated; was almost black and on being placed in water sank; it was very friable; had been attached to the upper and front wall of the chest; the right lung was normal or nearly so; the liver was enlarged, slightly lighter in color than natural, and weighed six pounds; in the abdominal cavity, in the lumbo-hypochondriacal region there was a quantity of serum; the omentum was puckered up and was slightly adherent to the diaphragm, showing that a limited peritonitis had existed; heart and kidneys normal; fibrin clot in heart.

The surprises were the great amount of pus present; the pathological condition of the lung; the ribs denuded at two points, and that life was so long retained despite such profound pathological changes. The left lung was absolutely of no physiological use, so that oxygenation was carried on by the right lung alone.

How soon did the lung collapse? Did it expand at all after the first paracentesis? Whence came the râles and the sibilant and whizzing sounds perceptible to within a few days of death? Was the enlarged liver due to septicemia or to the tippling to which he was addicted? Was the local peritonitis produced by some small perforation? Did it come from the pleural cavity above or was it the result of septicemia? What would have been the probable result had the cavity been tapped the day after the injury, when it contained pure blood from the wounded intercostal artery? Would the compressed lung have been likely to be restored a week after the injury? Was the large quantity of pus formed partly due to changes in the already accumulated blood?

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

TREATMENT OF PHLEGMONOUS INFLAMMATIONS WITH AN ALCOHOL DRESSING.

Dr. Salzwedel (*Centralblatt f. Chirurgie*, No. 45, 1894) is an enthusiastic advocate of a permanent alcohol dressing in phlegmonous and similar inflammatory conditions, claiming to have obtained with it ideal results. The inflamed region is washed with ether and a thick layer of cotton soaked in alcohol is applied. This is covered with an impermeable dressing material in which holes have been made to assist slight evaporation, otherwise the alcohol would act too caustically. A cambric bandage is then applied over the whole. The dressing is renewed every twelve to twenty-four hours according to the severity of the case; later, after subsidence of the swelling, every two or three days will suffice. Any open wounds may be covered with mull and over this the alcohol-soaked dressing be laid. A 60–90 per cent. alcohol is employed. The swelling and fever rapidly fall and abscesses form rapidly. These should be at once incised and the alcohol dressing be continued until healthy granulation or complete healing follows. Furuncles rapidly disappear or come to a head under this treatment; acute and non-tuberculous glandular inflammations also are favorably influenced. Suppurating buboes should not be tamponed with alcoholized cotton, as it is too caustic. In erysipelas it has given good results. Freshly infected wounds may be washed out with alcohol, for it penetrates into the depths and prevents the formation of abscesses.

POISONING FROM A BELLADONNA SALVE.

Dr. Melzer (*Memorabilien*, No. 6, 1894) prescribed a salve consisting of belladonna and lanoline (1:30) in a case of pruritus of the anus in a female. Although the itching soon disappeared, she had the salve prepared several times and continued to

*In charge of the translator, F. H. Pritchard, M.D.

use it daily. For several days she had complained of extreme weakness in her legs, dizziness, nausea, headache, a bitter taste in her mouth, great dryness and a scratching sensation in her throat, disturbances of sight and a sensation of great pressure over the eyes. The pupils were found to be dilated and her pulse increased in frequency. After discontinuing the salve improvement followed, with a complete restoration to health in several days. The skin around the anus was intact.

FORMULÆ FOR THE USE OF CHLORAL EXTERNALLY.

Dr. Brodnax (*La Semaine Médicale*, No. 63, 1894) recommends the following formulæ for the external employment of chloral:

In cutaneous pruritus from urticaria, measles or other eruptions:

Chloral.....	aa o | 50	grs. xijss
Carbolic acid.....		
Olive oil.....	o | 5 jss, gtts. xxx	

Apply locally.

In toothache:

Chloral.....	aa 5 | o	5 j 1-4
Camphor.....		
Carbolic acid.....		
Glycerine.....		

Introduce a ball of cotton moistened with this mixture into the cavity.

In earache:

Chloral.....	ãã o | 50	grs. xijss
Camphor.....		
Carbolic acid.....		
Castor oil.....	15 | o	5 iv

Instill a few drops of this mixture, previously warmed.

In acute coryza:

Chloral.....	o | 50	grs. xijss
Castor oil.....	15 | o	5 iv

If applied to the nasal mucous membrane after cleansing of the surplus mucus this mixture will arrest the secretion, calm the irritation of the mucous membrane as well as the accompanying headache.

TREATMENT OF INFECTIOUS DISEASES BY IRRIGATION OF THE NASO-PHARYNX.

Dr. A. Heller (*Wiener Medizinische Presse*, No. 47, 1894), believing that the majority of infectious diseases are caused by inhalation of the pathogenic germs and that their first localization is in the upper respiratory passages, has been in the habit during the past twenty-five years of employing irrigations of the naso-pharynx in these affections with the best results. He uses a simple rubber ball with a small tip and injects water which has been boiled and allowed to cool, though any disinfectant may be added. The temperature may vary according to the case. The head is held in the ordinary position and the stream is thrown horizontally through the open mouth two or three times on each side of the pharynx with a slight and equal pressure. The first irrigations are followed by a rapid fall of the temperature and a feeling of ease; the local symptoms, if present, also improve at the same time. The result is most striking in facial erysipelas and in various forms of tonsillitis. In diphtheria he claims that proper irrigation is able to act as a substitute for tracheotomy. He also recommends warm-water irrigations in whooping-cough, where they cause a rapid diminution of the attacks of coughing and a decided shortening of the disease; in scarlet fever and measles and in swelling of the cervical lymphatics, where there is often a naso-pharyngeal affection at the root of the glandular involvement. Also in tuberculosis, where the irrigations not only act as a preventive, but also as an actual therapeutic agent; in typhoid fever, articular rheumatism, etc. In pneumonia, bronchitis and bronchial catarrh he believes the irrigations to be an active expectorant. He finally advises their use in eczema of children, which he holds chiefly to be due to an auto-intoxication by the naso-pharyngeal mucus, as well as in the various facial neuralgias.

EXTRACT OF SPLEEN SUBCUTANEOUSLY IN MALARIAL CACHEXIA.

Dr. G. Cousin (*La Semaine Médicale*, No. 63, 1894), in two cases of malarial cachexia with considerable enlargement of the spleen which had resisted the usual measures, employed with success a filtered extract of the fresh spleen of sheep hypodermically. He commenced by injecting one gram of this extract, carrying the dose later up to eight to ten grams. These were made every day, and with the immediate result that the quantity of urine was increased, occasionally causing profuse sweats and a slight rise of temperature. Locally there were observed three times small nodules of the size of a hazel-nut. The spleen rapidly decreased in size, while the accompanying pains vanished, the appetite and strength reappeared and the

patients' weight and number of red-blood corpuscles were augmented. After about thirty-five injections the patients were cured.

TOBACCO-SMOKING IN DISEASE.

Dr. Jankau (*Zeitschrift fuer Krankenpflege*, No. 7, 1894) in many cases regards moderate smoking as indicated, and especially where there is an express desire. In the majority of surgical affections it is permissible, with exception of convalescence from operations upon the bladder and abdomen. Patients with diseases of the eyes, nose, throat or pharynx should never smoke. The internal diseases which would not permit smoking are peritonitis, typhoid fever and similar affections. In stomach affections smoking may be allowed if the smoke be filtered. Patients with organic heart diseases should smoke as little as possible. In lung diseases, under certain circumstances, he would hold smoking to be indicated; also in syphilitics. In those with nervous diseases there is no general rule; sudden withdrawal often does harm, while in cardiac neuroses only a very weak tobacco with filtration of the smoke is allowable. To smoke in the sick-room where there are several patients present is hardly to be commended. The best time to smoke he would believe to be several hours after meals.

BELLADONNA IN SKIN DISEASES.

Dr. Eliza Dunbar (*La Semaine Médicale*, No. 63, 1894) has found belladonna, the use of which is almost limited to the treatment of itching affections of the skin by external application, also to be of actual value in certain other skin diseases. Thus she has succeeded in curing an obstinate case of exfoliating dermatitis and several cases of eczema, which had resisted the usual measures, with the internal and external use of the tincture of belladonna. In the management of pruritus of the vulva and other local pruriginous affections she has obtained good results with local applications of a mixture of the tincture of belladonna and the perchloride of iron or with an aqueous solution (10 per cent.) of the sulphate of atropine.

TO ADMINISTER CASTOR OIL AGREEABLY.

In the *Medicinische Neuigkeiten*, No. 45, 1894, in giving castor oil to children it is advised to pour the oil upon a lump of coarse brown sugar; the sugar soaks up the oil and disguises the taste. Adults might object to this sweet taste, in which case a pleasant emulsion may be made by shaking a teaspoonful of the oil in a bottle half-filled with warm milk; an agreeable emulsion is formed which neither tastes nor smells of the oil.

LOCAL TREATMENT OF ULCERATING SYPHILIDES.

Dr. Mauriac (*Revue Internationale de Médecin et de Chirurgie Pratiques*, No. 18, 1894) in the local treatment of ulcerating syphilides habitually employs the following salve:

Calomel..... }	āā 1	o	grs. xv
Oxide zinc..... }			
White vaseline.....	26	o	ʒvj, grs. xxx
Starch	3	o	grs. xlv

PERMANGANATE OF POTASH IN SNAKE-BITES.

Dr. Lacerda (*Norsk Magazin for Lægevidenskaben*, No. 10, 1894) advises the subcutaneous injection of a solution of permanganate of potash both around and into the bite in the treatment of snake-bites. In the very poisonous foreign varieties a 5 per cent. solution may be necessary. In adder-bites Dr. Selldén, a Swedish physician, has found a 1 per cent. solution sufficient. The injection must be done as soon as possible. Ligation of the bitten limb will retard the absorption of the virus, yet not over twenty-five minutes.

STRYCHNINE IN SNAKE-BITES.

Dr. James McNish (*Australasian Medical Gazette*, No. 3, 1894) reports the case of a butcher, aged forty-five years, who was bitten by a poisonous brown snake upon the hand. The man was of powerful build and not under the influence of fright from the bite. He had himself applied a ligature, sucked out and scarified the bite with his pocket-knife. He came to the office and while joking over the bite, after eight minutes he suddenly fell to the floor from the chair insensible, with dilated pupils and eyes turned upward. Fifteen minims of liquor strychninæ were immediately injected into the arm; marked improvement soon followed, so that with aid he could be moved about. He seemed very

sleepy and begged to be permitted to sit down a moment. Alarming dyspnœa soon developed, when another injection of ten minims of the strychnine solution was given; decided improvement followed. A second dyspnœic seizure came on accompanied by violent retching. He was then put under a cold shower-bath and brandy injected hypodermically. Breathing then became normal and he expressed himself relieved. Three further relapses then followed, which were treated by injection of strychnine, the cold shower-bath and black coffee. The next day he was over the worst and felt well beyond a feeling of nervousness, with slight weakness of the general nervous system, while at the site of the wound there was a sensation of numbness and tingling. The reptile was found to be a brown snake common to North Queensland, four feet six inches long, with well-developed poison sacs capable of holding ten to fifteen minims of poison; when examined they were quite empty. This is the fourth severe and genuine case of snake-bite which the writer has saved by the strychnine treatment. They were all accompanied by violent symptoms and could not be attributed to fright.

PERMANGANATE OF POTASH IN PHOSPHORUS-POISONING.

Dr. Antál (*Hospitals-Tidende*, No. 46, 1894) recommends the permanganate of potash as an efficient antidote to phosphorus. It alters the poison to phosphoric acid, which is comparatively harmless. It cannot be employed in concentrated solutions on account of its caustic properties, but he has observed from animal experiments that a 1:1,000 to 1:100 solution is easily tolerated. He administered a fatal dose of phosphorus to ten dogs; three were not treated by antidotes, yet received irrigation of the stomach. The other seven were treated, without washing out of the stomach, with a pint of a 1½–2:1,000 solution of the permanganate and administered from a few minutes to two hours after; this dose of the antidote was repeated three to four times. All seven recovered and remained in good health. In human beings he would advise giving at once from a pint to a quart of a 2–4:1,000 solution and to repeat the antidote a few times at half-hour intervals. Hajnos has employed this method in two cases of phosphorus-poisoning in man, administering the antidote a half-hour after. Erdoes, two hours after the drug was swallowed in a very large quantity, gave every five minutes a wineglassful of a 1–2:1,000 solution until in all four quarts were drunk. At the same time an injection of apomorphine was given and the patient recovered.

STRYCHNINE IN PNEUMONIA.

Dr. Percy Kidd (*La Sperimentale*, No. 34, 1894) speaks highly of the use of strychnine hypodermically in the treatment of heart exhaustion in croupous pneumonia and other acute pulmonary states of inflammation. It seems to have a sedative and strengthening effect upon the nervous centers controlling the heart and respiration. It will frequently succeed where alcohol and ether fail. He advises its subcutaneous use in doses of one to one and a half milligrams. The condition of the pulse is the chief indication. As soon as it grows small and frequent or the respiratory movements become feeble it must be injected. The results are apparent in ten to fifteen minutes in an increase of the force of the pulse-beat and the respiratory movements. Though in general one injection every twelve to twenty-four hours is sufficient, it may be administered more often, even every two hours for three or four times, to continue it at longer intervals, as the occasion requires. In alcoholic patients it also acts well, calming the delirium and giving the heart and respiration increased strength by its action upon the cardiac and respiratory centers.

STERILIZATION OF CATHETERS.

Dr. Kutner (*Muenchener Medicinische Wochenschrift*, No. 45, 1894) advises exposing catheters to the action of hot steam as an efficient means of sterilization. Before one is introduced into the bladder an irrigation of the urethra must be made. For this purpose a 4 per cent. solution of boric acid is to be recommended. As a lubricant a borated glycerine he has found most serviceable. This is prepared by adding 146 grams of anhydrous glycerine to 150 grams of a 4 per cent. solution of boric acid; boric acid is then added to saturation.

BORAX IN EPILEPSY.

Drs. G. Angelucci and A. Pieraccini (*La Sperimentale*, No. 31, 1894), after an extensive use of borax for three years in the treatment of epilepsy where careful record of the number and intensity of the attacks was kept before, during and after treatment, have come to the conclusion that it is a very useful remedy in essential epilepsy, reducing the frequence of the seizures, sometimes suspending them entirely or substituting for the convulsions slight vertiginous attacks or "spells" of absence of mind. It rarely is inactive. It often moderates the character of the epileptic, rendering him more tractable and calmer. Its use should not be too prolonged, in general not over three months, and the dose should not exceed six grams a day, as it may give rise to grave stupor from which one recovers with difficulty. When signs of saturation of the system, as cutaneous eruptions, acne and eczema, desquamation of the skin and falling out of the hair, mucous vomiting, pronounced pallor of the forehead and a tendency to corpulency, appear, it should be immediately suspended. It is best given dissolved in warm water with a little sirup of orange three times a day, immediately after meals, commencing with sixty centigrams and then increasing to one gram, one gram and twenty centigrams, and later reaching two grams a day. Thus administered it will not cause disturbances of the stomach and intestines as when given in one dose at one time in the morning on an empty stomach. It also has the advantage of being inexpensive.

SCRUBBING OF INFECTED WOUNDS.

Dr. Ramm (*La Semaine Médicale*, No. 63, 1894), in order to obtain disinfection of tuberculous wounds or those which have been infected secondarily, advises scrubbing them energetically with a sterilized nail-brush dipped into an antiseptic solution. He has obtained excellent results with this measure.

TRUSS PADS FILLED WITH GLYCERINE.

Dr. A. Landerer (*Centralblatt fuer Chirurgie*, No. 41, 1894) for the past four years has been using trusses with pads filled with glycerine with satisfactory results. Their form is the ordinary one; the pressure exerted is soft, more uniform and yet more forcible than that of the usual pads. In contrast with those they never become hard and are also quite durable, lasting for one and a half years. They have the advantage over the ordinary ones in that they do not thin the tissues about the ring. In several persons over thirty, with ruptures of the size of a walnut, he saw them disappear in one to one and a half years under the use of these pads, a result he had never obtained with the hard pads. This form of pad is also applicable in umbilical hernia and in movable kidney.

TREATMENT OF CARDIAC AND VASCULAR NEUROSES.

Dr. Determann (*Sammlung Klinischer Vortræge*, Nos. 96, 97) has observed in two years 54 cases of distinct neuroses of the heart and large blood-vessels. Men were chiefly affected, and particularly those whose occupations as merchants, speculators, etc., exposed them to emotional excitement. Anemia was generally present and the general causes those of neurasthenia. Emotions were usually the exciting factors, though it may be a reflex from other affections, as those of the digestive tract, sexual organs, neuralgias and the so called spinal form of neurasthenia. In rare cases a too elevated region may be the cause. Organic symptoms, as murmurs, extension of the heart's dullness and arrhythmia, are quite rare. The pulse-rate may rise upon slight excitement to 96 or 100 a minute, though at the beginning of the attack it may be slowed, especially after fright, with a reaction setting in with increased pulse-rate, changes in the color of the face and hands, paresthesiæ in the hands and feet, precordial anxiety and dyspnœa. In time the second or paralytic stage is reached, where the pulse is continuously high, 96–120, even occasionally at 140 and over, with a weak beat, the vascular tonus decreases, there is paleness and coldness of the peripheral parts, the nutrition suffers and sleeplessness sets in with depression of mind and irritability. Slight bodily exertions, as arising from a chair, turning around suddenly, or sudden emotional impressions, will then provoke an attack. The irritative and paralytic forms may be mixed. Diagnostically, myocarditis and sclerosis of the coronary arteries will offer

some difficulty. A transition of these grave nervous states to actual organic disease he regards as not improbable. The prognosis is not unfavorable with proper treatment and continued attention to hygienic rules. Its course is long and relapses are frequent. Treatment must be chiefly psychic; the causal affection must be kept in mind and removed. The nutrition must be regulated, with plenty of fresh air and exercise. The various preparations of iron and arsenic with valerian are of service, together with hydrotherapeutic measures, electricity, gymnastics, massage of the heart and residence in an elevated region.

CORRESPONDENCE.

INEBRIETY.

EDITOR MEDICAL AND SURGICAL REPORTER—SIR:

In looking over some numbers of THE REPORTER of a year ago, I notice an article from the pen of Dr. Wigginton, of Waukesha, Wis., on this well-worn but still important subject.

"The drink problem of this country is of vast proportions," truly says Dr. Wigginton. "The vice of intemperence certainly demands the best thoughts and efforts and work of philanthropists in this as well as every other country. The misery, the suffering, the degradation, besides the untold and uncounted millions of money, speak for it a more than passing notice."

The one fact, however, that remains through all this, evident to every one, is that all that is necessary to remedy this evil is for men to abstain from the use of intoxicating drinks as a beverage. The arguments the writer uses to prove that inebriety is a disease instead of a vice are specious and have been used again and again by theorists, for it is *not* admitted, even "pretty generally," that inebriety is a disease. The author says inebriety is a disease governed by pathological causes the same as any other disease. He, however, does not mean to say that every man who takes a drink or even one who gets drunk under tempting circumstances is an inebriate.

Where would Dr. Wigginton draw his line of demarcation? I have seen men who could drink a half-gallon or more of whisky every day and still be able to attend to business, while others would get gloriously and even beastly drunk on a half-pint or less. What would the doctor do with these cases? The one man, as I have absolutely known, often would be strai h to all appearanees in the evening after having drunk a half-gallon or more; the other with a "jag" of gigantic proportions on a half-pint.

Dr. Wigginton claims that the causes of this disease are predisposing and direct or exciting, the chiefest of all being heredity. Let us consider this. He admits that a child born of intemperate parents need not of necessity inherit this disease, leaving us to infer that after all inebriety may be a vice. Leaving out sex, nationality, etc., as predisposing causes (for we propose to speak more particularly of heredity), we pass over most of his arguments, for if heredity be a true cause, then all others must be subordinate to it.

The drink habit is admitted to be almost wholly confined to males. How often do we see a man foolish enough to make a beast and worse of himself, of whom some one will say: "Oh, well, no wonder he drinks. His father or grandfather was a drunkard." This man, perhaps an only son, may have a half-dozen or more sisters, not one of whom has inherited this disease. In fact, no matter if the father and grandfather and all ancestors for hundreds of years back had this disease, the girls never inherit it. Oh, no! They may be puny and sick in body; they may and do have sorrows and troubles no man can ever dream of; they may be married to men who have inherited this disease who starve, maltreat and abuse them, but Dr. Wigginton nor any one else ever saw a case of heredity in a woman. It does seem strange that with all the cases of so-called heredity women are "not in it." One would naturally suppose, with her finer nervous organiza-

tion, her numerous diseases, unpleasant and painful beyond anything a man can feel, her greater temptations, with pregnancy, child-birth and the suffering incident thereto, woman would be affected with hereditary inebriety if there be such a thing. But who ever heard of such a thing in woman? In thirty years' practice I never saw or even heard of one case that could even remotely be accredited to heredity. An intemperate woman can always trace her disease to man's lusts, not to heredity; and with her virtue all she has in this life is gone.

When Dr. Wigginton speaks of environment, he strikes the keynote of the cause of ninety-nine out of every hundred cases of inebriety. Few men get drunk alone. Usually, in fact almost universally, men want some boon companions to make merry with them; and a boy or young man invariably, no matter whether his propensity be accredited to heredity or to deviltry, begins his drunken career in company with kindred spirits at a political meeting, Fourth of July celebration or social gathering of some kind. It is a very poor excuse or reason to attribute such cases to heredity. If the boy or young man had had different environments he would have remained sober.

Then, more nonsensical than all else, is the assumption that a man who is a drunkard cannot quit the beastly habit without treatment, let the cause be heredity or environment. He *must* abstain from the use of intoxicating liquor, even if he be treated by Keeley or somebody else. I knew a man who had been a drunkard for more than thirty years, drunk every day in all that time, who quit all at once and without treatment of any kind. This man had a good-paying business, but he drank up all the profits. He, as I said, simply quit drinking. He traveled all the time in connection with his business, accumulated property and was doing well again. He never kept away from places where liquor was sold and drank. He loafed about saloons and bar-rooms, but he never drank a drop. He lost all he had in the terrible Johnstown flood, but he came through and remained unscathed so far as his resolution to remain sober was concerned. Neither heredity, nor environment, nor adversity affected this man. He has solved this problem of inebriety, this disease so called, to his own and to every unbiassed person's satisfaction. This man's whole system had been saturated with the morbific poison arising from the constant use of enormous quantities of whisky, yet he had no trouble to break the chain that bound him.

This man was constantly surrounded by boon companions, men who had the "disease" in its worst forms. He was a jovial, good-natured fellow, a great story-teller, with a big heart and a purse open always to "treat" any one who would drink. Yet to-day he is a sober man and a respected citizen, and that too without any treatment whatever, without religious inclinations of any kind, for unfortunately he is a very profane man. He simply determined to stop this vicious habit and show his legions of friends he was a man and not a brute. I inquired of him whether he was not tempted sometimes to drink. He said he was, but that he was man enough to overcome all temptations, and I believe he is. This case, which I have specified at length, is only one of dozens I could mention in my own neighborhood.

Cannot any man do this? Is it not nonsense to talk of any man's inability to stop a vicious habit without resorting to treatment? Of course no intelligent person will attempt to deny that after years of whisky-drinking and debauchery the system will become diseased. So will it if any other vice is continued for a length of time, but the difference between inebriety and other diseases lies in this fact: No matter whether the disease be epidemic or endemic, the system becomes charged with a certain morbific poison—germs, bacilli, microbes or whatever it is—from without, or at least the poisonous matter enters the system in a manner involuntary to the sick man, whereas in this disease inebriety the patient deliberately takes the poison into his system. He can secure immunity from the disease without inoculation, or he can eliminate it after infection by simply abstaining from the use of intoxicating liquor.

Dr. Wigginton truly says that "to summarize, we might say environment is the exciting cause and covers the whole subject." "Bad associates," he says, among other things is a cause, and I think we need seek no further for the direct and the main cause of drunkenness. Let a boy or young man keep away from evil associates

and he will never get drunk. Oftentimes we see a big strong man, after a business reverse or some trouble, death perhaps in his family or a little domestic misunderstanding with his wife, in which he is usually the aggressor, go off and get drunk and keep on getting drunk until he has this disease Dr. Wigginton discusses so learnedly. Does his wife, too, get drunk on a like provocation? Nay, verily! She bears up under a load of trouble her puling husband could not understand, and keeps her grand womanhood and her virtuous character unsullied. While her husband, with his "heredity" or "environment," is spending his money to get this disease, money his family sorely needs, she, with *her* "heredity" and *her* "environment," is doing right as "God gives her to see the right." Nobody pretends that this "disease," after years of immorality and vice, can be gotten rid of in "three or four weeks." The doctor says because a man suddenly stops getting drunk it is no sign he is cured of inebriety. He is right. But if the man stops and continues to stop he will be cured.

The author's recommendations for the cure of this disease seem to me, while harmless and good enough, to be rather visionary. The *drink habit* is certainly a serious one, and its solution calls for the best thoughts of statesmen and scientists, but it appears to me that the right thing has never been tried. I would not pretend to say what more would be right than to convince men that they wrong their God, their country and themselves by the continuance of this vicious habit. No man can make me believe that one ever lived who *could* not quit the drink habit if he *would*. To teach men that this vice is a disease and giving them a license to revel in debauchery and crime because of heredity and a presumed inability to help themselves is certainly a wrong to morality and to society.

I can remember as a boy in the community in which I live when within a radius of three or four miles there were twice that number of distilleries, and that the exception was to find a really sober man. Now there are but few distilleries in the county, and a habitual drunkard is the exception. Then not a house could be found where whisky was not used as a beverage. Now scarcely any one uses it. The liquor traffic in Pennsylvania is regulated by a wholesome license law which if enforced is almost practically prohibitory, and any one can see the great reformation that has been worked out in the last two or three decades. Science, philanthropy nor anything else can eradicate this evil until it is looked upon as a vice and not a disease.

WM. F. MITCHELL, M.D.

Addison, Pa.

Longevity and Drink.

The British Medical Association has been investigating the question of longevity in connection with the use of alcoholic beverages (*Med. Rec.*). Deaths to the number of 4,234, taken at random, show the average age of temperate drinkers to be sixty-three years; careless drinkers, fifty-nine years; free drinkers, fifty-seven years; intemperate drinkers, fifty-three years; total abstainers, fifty-one years. The analysis in the case of those who reached the age of over eighty shows that 15 per cent. were total abstainers, 10 per cent. heavy drinkers, and 74 per cent. moderate drinkers. Of those who lived more than ninety years, 15 per cent. were total abstainers, 9 per cent. were hard and 75 per cent. moderate drinkers. These figures must be applied with some caution. A certain large proportion of total abstainers are so because of some form of ill-health or natural weakness.

Tubercle Bacilli in Butter.

A Swiss physician introduced butter made from the milk of a tuberculous cow and containing tubercle bacilli into the abdominal cavities of guinea-pigs. The guinea-pigs died of tuberculosis. He then bought butter from various markets and injected five to ten centimeters of it into the abdomens of guinea-pigs. Two out of twenty specimens of butter were found to contain virulent tubercle bacilli.—*Boston Med. and Surg. Jour.*

Men and Women.

Twice as many women as men are afflicted with neuralgia.

Men are more liable to insanity than women, but after becoming insane die sooner.

Phthisis and pneumonia are more frequent and fatal among men than among women, while cancer and apoplexy kill more women than men.—*Med. Age.*

PENFIELD PUBLISHING COMPANY
Publishers.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JANUARY 5, 1895.

EDITORIAL.

SENSATIONAL NONSENSE NOT SANITARY SCIENCE.

Occasionally medical scientists, by enthusiastically accepting some alluring but specious proposition prematurely, have allowed themselves to be swept into practices unfortunate for their science and disastrous to their patients. The tuberculin treatment for tuberculosis is an illustration of such an error.

Much more common are exhibitions of what may be termed burlesque science—irrational and illogical deductions from established scientific premises. Preventive medicine seems to afford peculiar opportunities for these pantomimic displays. It may be questioned whether medicine eventually is not benefited rather than embarrassed by these performances of science *bouffe*. Certain it is that they who in the name of science commit such folly and seek notoriety as public alarmists, are oblivious to the truth of that homely saying of Abraham Lincoln, "One may be able to fool some people all the time and all people some of the time; but one cannot fool all the people all the time." The public press, which is the agent most frequently employed in circulating these pseudo-scientific dicta, is at the same time the factor most potent in exploiting their fallacies.

Perhaps there is nothing to which an American community is more sensitive, or which receives more the scrutiny of individuals, than those regulations of law or ordinance enforced as special protection against possible or imminent danger to the common health. The public sentiment which supports these regulations is the result of progressive education, and in this development the press is the most important factor. In matters of public health the lay press relies for proper direction upon current medical literature, and is prone to amplify and exaggerate whatever information is there obtained. Hence it behooves medical bodies and medical journals to be circumspect in their utterances and to con-

fine themselves to unadorned facts in their deliverances. The public is not accustomed to discriminate between real medicine and newspaper medicine, and the sayings of medical men or associations delivered to the lay press direct are but cheap biddings for notoriety. Whatever *eclat* is gained is at the unnecessary expense of public alarm.

Of late we have experienced an endemic of calamity howls which would have been regarded jokes but for the sources whence they arose. For instance, the following resolution, recently adopted by a medical society, certainly displays much more of anxiety to attract attention by making a great noise than of good professional knowledge or practical common-sense. The resolution recommends that "the Board of Education abolish the common drinking-cup in the public schools, the Park Commission do away with drinking-cups at springs, and railroad companies remove the common drinking-cups from all stations and trains, to prevent risk of contamination and teach the public to adopt and use individual drinking-cups."

This is a not unfair specimen of the sensational nonsense sometimes offered the public as sanitary science. It is a result of the thoroughly unscientific methods and egregious incompetency of those precocious ones who receive, without comprehending fully, an hypothesis probable in the abstract, and promulgate it as a general law positive in the concrete. There may be some extenuation in the case of our friends whose conception of the supreme spirit of medicine is a diluted Dynamis, and whose scientific faith predicates infinite potency of the infinitesimal. But it is not science in the ordinary acceptation of that much-abused word.

We do not feel called to defend the rust-corrupted tin cup of the public school, nor the galvanized solder ladle at the park fountain, nor the battered leaden antiques which adorn some railroad stations and cars, but these are offenses against public decency rather than menaces to public health. To abolish articles so absolutely essential to public convenience and comfort may be sound theoretically. When reduced to practice, however, factors must be taken into consideration which modify the theorem to such an extent as to render it impracticable. These modifying factors will determine the verdict of the public in its estimate of the utility of the proposition.

That dangers may exist in the water supplied there can be no reasonable doubt. But the resolution does not contemplate dealing with the water. There appears to be no authentic record of the probable transmission of infection by the utensils mentioned *independent* of a contaminated water supply. Nor are we aware of an instance where in the researches of the bacteriological laboratory there has been discovered and identified any infective germs obtained from one of these public drinking-cups. Before advocating a measure which would produce an enormous amount of public inconvenience, discomfort and suffering, it would be well for astute aspirants to popular scientific repute to establish (1) the probabilities of these cups becoming infected in the course of their ordinary use; (2) the probabilities of retaining infection despite the disinfection by constant flushings with water and by exposure to the atmosphere; (3) the probabilities of users becoming infected under the necessary conditions demonstrated by present knowledge of infectious processes. When the risks can be shown to have more than a theoretical existence and a present danger can be urged against undeniable merits, science will be found ready to suggest a rational remedy.

The alternative proposed, viz., the possession and use of individual drinking-cups by each and every human being, is so

manifestly inconvenient and impracticable that we are impelled to advance a suggestion in aid of our scientific friends whose cerebral powers were overstrained before a simple, universal and easily applied specific was devised. Being a novel application of an old principle, perhaps some speculative sanitarian can take out letters patent and find his own reward while benefiting others.

In general terms the apparatus may be described as consisting of a hole of any desired dimensions, surrounded with a casing of any impervious material, rigid of flexible, and fitted with a sterilizer at one end and a sucker at the other. It is needless to specify the innumerable forms in which this principle may be applied, but it is evident the lady of fashion may wear her individual drinking conduit as a jeweled hairpin or as a bracelet; the business man may carry his personal aqueduct in the same pocket with his fountain pen; the dude may secure another function for the sapling he uses as a balancing pole when his hair is mussed, and the urchin will not neglect a utensil which can be utilized as a blow-gun.

Moreover, the Board of Education, the Park Commissioners and the railroad companies could, at a trifling expenditure, provide abundant individual conveniences for the improvident and for the strangers within their gates, by supplying quantities of the wax-paper straws commonly seen at soda fountains and other repositories of uncontaminated liquid refreshments.

Another manifestation of sanitary insanity is a folly which amounts to sacrilege. Even the sacramental cup has been accused of conveying infection. Suffice it to say that the accusation is evidently brought by parties having no personal knowledge of the institution. Throughout all the centuries, while millions have obtained comfort and blessing by partaking of the holy communion, there has never been recorded a single instance of the transmission of infection by the cup of the New Testament. There is absolutely no justification for agitating this matter in our present knowledge.

Apart from these flippant fancies there is abundant food for thought presented in the operations of scientific health precautions under the direct supervision of conscientious and fully qualified sanitary scientists.

There is a risk that what is called scientific medicine may be pushed to the point of scientific fraud and plunder. Public health measures must be not only rational, but humane, or they will fail of support from public sentiment. The advocacy of extreme measures tends to breed indifference rather than rational caution; each unreasonable or too severe health regulation encourages and stimulates the concealment of conditions most dangerous to the community from a health standpoint. In cases of certain contagious diseases a form of quarantine or isolation may be enforced which proves too severe and even oppressive. The rights, family ties and interests should be scrupulously guarded in the enforcement of health regulations. It is not an impossible occurrence, not even an improbable one, that a workingman, one whose family is dependent upon him for support, who has no resources other than his personal labor, may be quarantined, penned in the narrow walls of his home with his poverty, disease and distress, while some loafing ward heeler and political sycophant is liberally paid to guard the doors that bar in its poverty and need. This may happen to many a poor man while the rich and influential walk abroad unhindered. There are no immunities from legal quarantine which the rich should enjoy over the poor.

Our citizens are sufficiently intelligent and alive to the importance of wise health laws and of the value of their efficient local and general administration of the health

of our population to recognize that isolation in many cases of contagion is important, and against it there neither could nor would be complaint. Where this is required of the poor their limited means of subsistence should be carefully considered and destitution guarded against. A humane, scientific and common-sense application of our existing knowledge of the causes of disease as affecting masses of population, this knowledge crystalized into simple health regulations and circulated among rich and poor would distribute knowledge of health conditions and tend to eliminate whatever may be offensive in sanitary administration. To promote public hygiene our sanitary laws must have a wisdom and justice in them appreciable by the masses of population, and their execution must be tempered by a spirit of the highest public good.

There is nothing more offensive to communities than to be brought too rigidly under the ban of law.

Uncleanliness and slovenliness are not habits with our people, therefore our immunity from many filth infections. Yet constant vigilance is required on the part of our health authorities to guard against those nuisances sometimes intentionally, more frequently unintentionally, stored out of sight.

With all the vigilance of our sanitary administration we have not yet reached that ideal cleanliness suggestive of the best hygienic conditions. "The entire number of complaints of nuisances received and entered upon the records was 33,119. This includes complaints received from citizens, nuisances discovered by the house-to-house inspection, nuisances reported by the medical inspectors and those reported by the Bureau of Police."

The annual report of the Board of Health for 1893 made an excellent showing as compared with past years, and we can safely anticipate, from present health conditions, the more efficient dealing with nuisances and rigid exercise by the authorities of sanitary functions, a better report for the current year, 1894. During the year (1893) the death-rate per thousand was 21.20, or one (1) death to each 47.15 living persons. The Board of Health was fully justified by the facts in making in their report the following statements, which have an interest for the medical profession as well as the general public: "It may be said without contradiction that in no period of the history of this country have the maritime defenses against the introduction of dangerous communicable diseases from abroad been so complete, and the organization of sanitary boards and the efficiency of sanitary work been so wide-extended and so thorough. Not only was the strictest attention bestowed upon cleanliness of the public thoroughfares and places, but extraordinary effort was made to get rid of nuisances upon private premises.

"It is sufficient to say that by the united efforts of the authorities and the people the work of purification constantly progressed, leaving as its reward a condition of health which was a marked improvement over many of the preceding years."

When it is considered that the air we breathe is filled with all the detritus that comes from the wear and constant travel over our old cobble-stone street pavements, all will appreciate the strong language of Mayor Stuart in one of his messages: "Liberal appropriation enabled miles of improved paving to be laid in these small streets, and from the standpoint of practical municipal philanthropy in improving the health and surroundings of the people living in these streets, it is, in my judgment, the most important work accomplished during the whole year. The houses there are as a rule very closely built and the residents compelled by their circumstances to remain there during the heated period. Heretofore it was utterly

impossible with the cobble-stone pavements and their defective drainage to keep them clean enough to even approach a sanitary condition, and besides, it was hardly humane to compel our fellow-creatures to live among such municipal surroundings. In my judgment there has been no money so wisely appropriated, and you could appropriate no amount too large for thus improving the small streets in all sections of the city."

Thus it will be seen that there has been a very general carrying out, as far as means were afforded, of sanitary obligations. So the alarm gentlemen, with their little fads or hobbies, can indulge in their small scientific amusement without startling the world by their discovering some new lurking enemy to human health and happiness, and they may find by-avenues to public notice without exciting more than amusement or ridicule.

ABSTRACTS.

NURSING IN ABDOMINAL OPERATIONS.*

MARIE ERNESTINE WELCH, TACOMA, WASH.

Surgical nursing is divided into two great classes: General surgery, which embraces fractures, amputations, burns, etc., and abdominal surgery—the operations on the abdominal or pelvic organs.

For my subject I shall choose nursing in abdominal surgery.

Under this head many different operations can be performed for which a skilled nurse is required—as removal of uterus and appendages; the uterus itself; the ovaries and Fallopian tubes—all or one—cysts, tumors, appendix, portion of the bowels, spleen, etc.

The kidney is removed sometimes, but usually the incision is made on the side—almost under the arm, a trifle toward the back, instead of in the median line.

Operations on the stomach, gall-bladder, pancreas, etc., are also classed under abdominal section.

The uterus and its appendages are sometimes removed through the vagina; but where adhesions are suspected it may be necessary to open the abdomen.

The duties of the nurse in such a case are a matter of great importance.

She must realize the gravity of the case and must be exceedingly careful that no complications arise through any oversight or neglect on *her* part. She must be gentle and kind, cheerful and sympathetic. While she must do all she can to reassure the patient, she must not be too confident of success, nor must she fail in carrying out the *minor* details.

Germs invade almost all, if not all, places. If we render everything aseptic—germ-free—then we are sure, if anything should occur, that it was through no fault of ours.

Sometimes, despite all we may do, our patients die; but it is a source of great satisfaction to know we were blameless.

When operations are to be performed the nurse usually presents herself at the appointed place two days before the time fixed for said operation, and not less than twenty-four hours before the time, in order to make the necessary preparations, etc. First she will see the patient and get a full history of the case for the compiling of the chart; take temperature, respiration, pulse and examine the stools and urine carefully. Her data must be exact, and if she notices anything to lead her to suspect kidney trouble, she must immediately inform the physician.

The safest and wisest plan is to send a specimen of the urine and have it analyzed before the operation is done.

The heart and lungs of the patient should also be thoroughly examined before the anæsthetic is administered; and should the physician overlook this in his preoccupation, it is the nurse's duty to call his attention to it.

The preparation of the patient I shall first consider. The physician or surgeon

*From Trained Nurse, October, 1894.

will give the nurse certain directions, which must be carried out *to the letter* and will read something like this: Bathe patient antiseptically; shave the mons veneris and vulva; give vaginal douche and enemas enough to empty the bowels. (A mild purgative also will sometimes be ordered.) Place bichloride pad 1:200 over the field of operation for twenty-four hours preceding operation. Give no food for at least six hours before the operation, etc.

The mons veneris and vulva should be shaved the evening before the operation, and a thorough bath given. Scrub the parts to be operated on and the neighboring vicinity with soap and water applied with a new brush. Next, bathe these parts with ether or alcohol and over them place the pad—a piece of antiseptic gauze wrung out of bichloride solution 1:200. The pad must be large enough to entirely cover the whole abdomen, from the sternum to the pubes bone.

The hair should also be thoroughly washed and dried. The patient is then given the purgative, if one has been ordered, and she is then left to sleep. The next morning, early, the enemas are given. These may be plain warm water, soapsuds, warm water with an ounce of glycerine, or just an ounce of glycerine with enough water added to permit its passage through the syringe. This sort of enema is generally followed by plain warm water after a little time has elapsed.

The vaginal douche is then given, after which the patient rests for a short time, while the nurse proceeds with some preparations in the operating-room. About two hours and a half before the operation the nurse will give the antiseptic bath in sterilized water placed in a sterilized bath-tub. Prepare seat of operation the same as before, by bathing off with alcohol or ether and reapplying new pad. This pad must not be removed until the patient is on the table and the surgeon directs its removal.

One hour before the operation the last enema and douche should be given, and the patient is then put into a sterilized bed, after having been dressed and her hair neatly and tightly braided *à la* Marguerite, where she is to remain until ready for anæsthetization. Just before the anæsthetic is administered the nurse should catheterize her and remove false teeth.

The clothing of the patient consists of an undervest, a pair of leggings made of muslin and a short flannel sack or night-dress. The leggings must reach to the hips. These are very nice, as they protect the limbs from cold and exposure. All the clothing of the patient, beds, operating-table, sheets, towels, nurse's clothes, etc., must have been thoroughly sterilized.

A sterilized blanket must be ready to cover the patient, covered by sterilized sheets.

Having now completed the preparations for the patient, we will consider the nurse. She must go to the case in as perfectly a sterilized condition as it is possible to attain, having taken an antiseptic bath, hair having been thoroughly cleansed and all her clothing aseptic.

She should take with her a cook-book, a clinical, room and water thermometer, bed-pan, catheters—glass and soft rubber No. 7—a rectal tube, fountain syringe, ice-cap, hot-water bag, Wilson charts, dressing-pans, two—one for solution, the other for soiled dressings—bichloride tablets 7½ grains, carbolic acid 95 per cent., graduating glass—large—etc.

She must never enter the room in which the operation is to be without she is in a perfectly aseptic condition. She must take especial care of her nails, for they often contain septic material which might be transmitted to the patient.

She must always present a neat, clean appearance and her linen should be immaculate.

We have now reached the stage for preparing the room for the operation. This should have been cleaned and all furniture, carpets, draperies, etc., removed. The room should then be closed, door locked, but before so doing the windows must be thrown wide open, so that plenty of fresh air may fill the room.

It should be left this way for at least from twenty-four to forty-eight hours before preparing the room for the operation.

In selecting the room, be sure of several things. First, that no contagious disease has been in the room at any time. If there has been, it must first be thoroughly disinfected by sulphur. Second, the room must be very light, with abundant ventilation and means of heating if necessary. A room with a southern exposure is considered the best.

The furniture of the room will consist of the following articles: Three small tables, one each for sponges, for dressings and for instruments. A long narrow table is required for the operation, and over this the surgeon sometimes places a frame —to represent a laparotomy table—and by raising this he can put his patient in the Trendelenburg position, lowering the head and raising the knees. By this method the intestines are forced toward the diaphragm and are out of the surgeon's way in operating. A chair, a bench or a table is needed on which solutions can be placed ready for use. The bed for the patient, if she is to occupy this room after the operation is over, must be placed where it will be out of the way during the operation. Besides what has been already mentioned, there must be a wash-stand (with towels for surgeon and assistants to sterilize their hands) and a stool on which a basin containing sterilized water must be placed for surgeon's hands during operation.

These articles, after having been thoroughly cleansed, are brought into the operating-room. The nurse will then proceed to wipe floor, ceiling, walls and every article of clothing with a cloth wrung out of bichloride solution 1:1,000. Each time she leaves the room she will fasten the door so no one can enter.

All china, glass, in fact everything used must be sterilized; therefore boil said articles. Turn bowls, etc., upside down and cover then until ready for use. Two wash-bowls and pitchers are needed —one bowl for surgeon's hands and the other for his assistants. One pitcher will contain boiling water and the other cold sterilized water. If permanganate of potash is used, have some oxalic acid on hand to use for removing the traces of the permanganate.

Three basins should be within easy reach—one for washing sponges if sponges are used, one for the bichloride solution and a third for the sterilized water. The sponges are passed to the assistant after coming out of the sterilized water.

Have a small gasoline stove on hand with pan of hot water ready, so that if any instrument needs sterilizing it can be done at once. Two instrument pans, also one for needles, sutures, etc., are necessary, and an irrigator which will hold not less than one gallon of solution or sterilized water.

A perineal pad is nice, with the long flap dropped in a bucket to carry off the water, discharges, etc.

Have a good-sized foot bath tub and a couple of slop-jars to empty the soiled water in.

Four dozen towels are usually required, and five sheets will be needed. It is best, however, to have two or three extra ones on hand.

One dozen towels should be ready to be dropped into bichloride solution.

Be sure all the linen has been rendered aseptic.

Now, as to the solutions and smaller articles. Have plenty of water.

The day before the operation the nurse should prepare that which is to be used cold. *Boil* it for one hour, then strain three times through sterilized cloth into sterilized receptacles, and when this is done cover and tie cover down. Do not remove until the water is required for the operation. About five gallons of cold sterilized water will be needed and four gallons of boiling water, which must also be strained.

If solutions are ordered get them ready, label them and color all poisonous solutions. Keep them covered. In fact, cover everything of this kind.

Have soap-dish, Castile soap, two or three small, new nail-brushes, and be sure a thermometer is in the room. The temperature must not be below 80° nor above 90° F. A warm room is necessary on account of shock. Have plenty of hot-water bottles ready for use.

A small tray should be prepared, having on it a hypodermic syringe, nitro-glycerine and strychnine tablets, brandy and distilled water. This tray must be placed so that it can be used at a moment's notice. Just before the patient is anæsthetized the nurse may be directed to give her—hypodermically—grs. ¼ morphia, atropia 1:200 or a drachm of brandy.

About three nurses are required at the operation. Sometimes a fourth one is asked for. One is needed for the instruments, another for the sponges and a third to wait on the physicians and nurses.

Three physicians are usually present, the operator, his assistant and the anæsthetizer. It is better for the nurse in charge of the case to assume charge of the

room and let one of her assistants pass the instruments, for she can then be on the watch constantly to supply anything that may be required.

As she has been there for several hours, she will best understand where things are. Each nurse will pay strict attention to her own part of the work, and if this is observed there will be no confusion.

The nurse who passes the instruments must not touch anything else. She must be surgically clean.

The surgeon will be too much occupied to notice everything, so the nurses must be extremely careful not to touch door-knobs, etc. If it is necessary to do so, the hands must be sterilized immediately.

The patient is usually anæsthetized in bed, in another room. One nurse and the anæsthetizer will remain with her; the other two will complete the work in the operating-room and wait on the physician.

When everything is ready and the patient is unconscious, she is carried to the table, which has been covered tightly with a blanket and a sheet, said articles being separated by a piece of mackintosh. Over this is placed the perineal pad. The table is placed near the window with the feet of the patient toward the light. If, however, Trendelenburg's position is desired, the head should be toward the window. The operator, the nurse in charge of the instruments and the instrument table are on the right side, the assistant physician, sponge table and the nurse in charge of this table stand on the left side.

The anæsthetizer's place is at the head of the patient. He must be supplied with pins, basin and towels, in case the patient should vomit.

The instruments are usually sent in an hour before the operation, and consist of the following: 12 prs. hæm. forceps, 4 prs. scissors, 4 retractors, 2 prs. dressing forceps, 1 pr. volcellum forceps, clamp for broad ligament, 1 groove director, 1 sequestrum, 2 aneurism needles (straight), 1 scalpel, 1 bistoury, needles, silk and catgut sutures, aspirator and drainage tube. A list must be made of the instruments. These must be boiled for twenty minutes, then lifted out with small pair of forceps and placed in the trays prepared for them, in either carbolized water, alcohol, pure or sterilized water. The blades of the scalpels, bistouries or those with sharp surfaces must be wrapped with cotton before they are boiled.

The needles can be put through a piece of gauze and boiled in this way. Silk ligatures and sutures are also boiled. Catgut, however, remains in alcohol.

After the patient is placed on the table the nurse will uncover the abdomen, removing everything but the pad.

The leggings must be pushed out of the way and the undervest and night-dress drawn up. The arms are folded across the chest and the sleeves pinned to the gown. The nurse then covers the limbs of the patient with a blanket wrapped in sterilized sheets.

The operator then removes the pad.

He may wish to have the parts rescrubbed; if so the nurse brings to him a basin containing water, also soap and brush. Should the nurse be directed to perform this part of the work, it must be done thoroughly, wiping off with bichloride solution 1:2,000. Over the abdomen place a piece of oiled silk with a hole cut in the center. This piece should be large enough to reach from the chest to the knees and from one side of the table to the other; then bring the bichloride towels. Wring them out of the 1:2,000 solution and cover the oiled silk with them. The opening in the oiled silk must be large enough to permit of the surgeon having plenty of room to work. This is very nice, as it protects the patient from the dampness and water. The surgeon then commences work. The head nurse must be ready to pass the bichloride towels when they are needed, to keep the irrigator filled with water of the proper temperature, about 100° F., and to change water in the sponge dishes, and, in fact, to carry out any orders.

The first nurse manages the instrument table, thread, needles, etc. The nurse in charge of the sponges must count every sponge and write down the number in use. Every one *must* be accounted for, because if one were left it would cause serious trouble, if not death.

Before the abdomen is stitched she must see that every sponge is in her basin. The first nurse must use the same care in regard to the instruments.

If any parts are to be amputated the nurse in charge of the room will pass a

tray with a towel on it to receive them, and after covering them they will be placed to one side. While the surgeon is closing the wound the nurse will get the dressings for him.

These are always prepared before the operation, wrapped in a towel, to be ready when called for.

These usually consist of a large piece of iodoform or bichloride gauze, some antiseptic powder, combine pads, some absorbent cotton to place over the pads and a many-tailed bandage. After the dressings are all on you can relax your vigilance (to a certain extent) in regard to germs.

The patient is then put in bed on her back with one low pillow, a towel under her head, and a basin and towels ready for emesis. The instruments are scrubbed and scalded, and all the *débris* and unnecessary furniture removed from the room.

The patient must be watched very carefully. Shock may occur; if so, give some slight stimulant and surround her with hot bottles.

Everything must be done to increase the circulation, but if hemorrhage occurs, withdraw the stimulants and place ice on the head. Remove the bottles, too, if they are around the patient.

In either case the first duty of the nurse is to send for the physician.

As soon as the patient's condition is normal after shock, remove the heat and discontinue the stimulants, as you may have the other extreme, fever, if you are not very careful.

Nurse's duties after operation are comparatively light, as all her work is done at the time of the operation.

The patient always gets along well, if her condition is favorable, when all the preparations have been thorough. She needs careful watching for several days and proper nourishment as well. The nurse may be obliged to catheterize her, and also give enemas when the bowels are to be first moved. If the patient be troubled with tympanites, the rectal tube, if introduced, will afford instant relief. Patients, as a rule, will ask for them a second time. They can be left in the rectum for fifteen or thirty minutes several times a day.

It is necessary to keep the patient quiet. If she has to be moved it must be done very carefully or there is danger of straining the stitches, which may cause them to tear out, besides giving the patient much pain.

The bed should have been so arranged as to permit changes being made without annoying the patient. Everything must be done to make her as comfortable as possible.

She will appreciate these efforts exerted in her behalf, and while at first she may be too sick to say much, she will soon be able to talk, and her first words will be t thank the nurse for her kindness.

No impatience should ever be shown with a patient, for unless one has undergone the same operation she cannot realize how much suffering has to be endured at such times, and when convalescing she will be only too willing to ask pardon for having been so irritable, if such has been the case.

A nurse should conduct herself in such a manner that she will reflect credit on her school and be an honor to her profession.

He chart must be carefully and neatly kept, food elegantly served, and she should have a note-book at hand in which to enter full notes of her case.

For the first three days the temperature should be taken every four hours; for one week, every six hours; then if the patient is getting along well, twice a day will be sufficient.

The urine must be watched and defecations as well, and their condition reported on the chart, in the note-book and to the physician.

The sick-room must be kept spotless.

The temperature of the room should be kept at about 68° to 70° F. and be thoroughly ventilated.

All sick-room utensils must be kept in another room. The medicines, etc., if kept in the room, must be covered with a napkin. Food must not stand in the room, but must be removed as soon as the patient has taken as much of it as she desires.

When the wound is to be dressed, everything must be in readiness for the physician when he comes, as he should not be kept waiting.

Care must be taken that everything is aseptic. If the abdomen has been closed the dressings well be slight, but if drainage has been used, careful handling will be required for several days.

Finally, all that is done do well.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

New Sign of Lead-Poisoning.

In eighteen out of twenty persons affected with lead-poisoning M. E. Destree (*Jour. de Med. de Bruxelles*) has observed a narrow zone of hyperesthesia at the level of the articulation of the manubrium with the ensiform cartilage. As a general rule, pressure on the sternum is readily painful only under one or two conditions—namely, when the bone is diseased, as is the case in leucocythemia with lesions of the bone-marrow, or when the thoracic wall and the skin are hyperesthetic, as happens in hysteria, sometimes in neurasthenia, and often in chronic alcoholism. But in these latter cases the hyperesthesia is not found to be so limited in extent as it is in lead-poisoning. Saturnine hyperesthesia is indeed a symptom of nervous origin, comparable to the intercostal neuralgias observed by Rosenthal. "There is nothing astonishing," says the author, "in the fact that the sternal hyperesthesia is so precisely marked, when we remember that Beau has shown that there is never any anesthesia at the level of the scrobiculus cordis in lead-poisoning, and that in lead colic there is a very decided hyperesthesia of the abdominal wall."

A Case of a Child Crying in Utero.

I desire to give a brief report of a case of the crying of a child *in utero*, in so far as I am able to ascertain a rather rare occurrence in obstetrical practice.

On May 16, 1894, I was associated with Dr. Wemple, of this city, in a case of confinement in South San Francisco. The mother had been in labor for some hours, the cervix was well dilated and the breech presenting. The natural forces seemed insufficient to effect delivery, and it was decided to perform extraction. Accordingly the mother was anesthetized, the hand introduced and the foot brought down.

As soon as the foot appeared at the vulva the cry of a child was distinctly heard by all present. The sound was somewhat muffled and seemed as though it came from under the bed. The cry was repeated a number of times, but ceased as soon as the head engaged in the superior strait.

Delivery was effected as rapidly as was consistent with safety to mother and child. The latter was born asphyxiated, but soon revived, breathed and cried again. There was no evidence of liquor amnii or mucus having been drawn into the air-passages. The child is now alive and well.

The explanation of this phenomenon is simple enough, for in the operation of bringing down the foot air entered the uterus and the child breathed and was so enabled to utter the cries.

In my limited researches on this subject I have been able to find but few such cases reported in medical literature. On February 6, 1894, Dr. Grandin reported a somewhat similar case to the Obstetrical Society of New York. In that case version was performed, but in all other respects the case was similar to the one just reported. In the discussion that followed, four other members each reported a case, and an important feature in these four cases was that in two the child perished during delivery. Dr. Grandin's case, with the discussion, may be found in the April number of the *New York Journal of Gynecology and Obstetrics*.

Another case of this kind was published in May, 1877, in the *Medical Press and Circular*. In this case the vertex presented and the forceps was applied. It is stated that the crying continued until the head was outside the vulva, which seems to me somewhat remarkable, as I scarcely see how the child could cry while the head was passing through the pelvis.

In a medico-legal way this subject may be of some importance, since the fact that a child has breathed, when proved by post-mortem examination of the lungs, is considered proof positive that it had an independent extra-uterine existence. In the two cases that died during delivery this would certainly be an error, for had the lungs been examined evidence of respiration would have been found, and yet both were born dead.—*San Francisco Med. Jour.*

Formulæ for the Antiseptic Treatment of Boils and Carbuncles.

Chloroform	ʒ j
Essence of cloves	m 75-ʒv
Creosote	m xv-xxx
Camphorated oil	ʒ ij

M. For external use only.

Salicylate of mercury	gr. ij-v
Salicylic acid	gr. xv-xxx
Rectified spirit	ʒ ss-j
Distilled water	ad. ʒ iv

M. For external use only.

The affected part is covered with compresses saturated with either of the above antiseptic mixtures. At the same time one or the other of the following solutions is injected into the boil or carbuncle:

Carbolic acid	gr. j-iij
Salicylate of sodium, Borax āā	gr. xv
Glycerine	m xxx
Chloroform water	ʒ ij

F. S. A.

Iodoform	gr. v-viij
Salol	gr. viij-xv
Carbolic acid	gr. iss
Ether	ʒ ss-j
Rectified spirit	ʒ iss-ij

F. S. A.

This treatment is said to give excellent results and to do away with the necessity for a more radical surgical intervention even in cases of carbuncle.—*Dr. E. Gourine in Med. Week.*

Salicylate of Sodium in Headache.

In the February number of the *Practitioner* Lauder Brunton writes an interesting article on headaches, in the course of which he points out that the one very common form of headache commences in this way: The patient sometimes feels a little unwonted irritability at night, but this irritability is not always present. It is very often the precursor of a headache. He wakes in the morning about four, five or six with a feeling of weight in the head, but not a headache. He is very drowsy, disinclined to rise, and is apt to turn over and go to sleep again at once. If he does this he awakes again about seven or eight with a distinct but not a severe headache, usually frontal or temporal. As the day goes on the headache becomes worse and worse, until in the afternoon or evening it becomes almost unbearable. It then finishes up with sickness, after which the patient becomes easier, but feels much exhausted. A headache of this sort may frequently be prevented by the patient taking a mixture of bromide of potassium and salicylate of sodium over night, or by getting up and taking it when he awakes with a heaviness in the early morning, instead of turning over and going to sleep again.—*Northwestern Lancet.*

Potassium Permanganate, the New Antidote to Morphine.

Dr. Graham Chambers (*Canadian Practitioner*) says:

Potassium permanganate in dilute solution, not stronger than one grain to an ounce, may be given by the stomach without danger.

Potassium permanganate, subcutaneously, is poisonous.

Potassium permanganate, grain for grain, completely decomposes morphine, the decomposition occurring in acid media more rapidly than in a neutral medium.

Foodstuffs and acetic acid do not interfere with the decomposition.

Potassium permanganate is an efficient antidote if taken while the morphine is in the stomach.

The question still remains as to whether potassium permanganate is of therapeutic use after the morphine is absorbed into the system. It has been proved conclusively that if morphine is introduced subcutaneously into the system it is excreted into the stomach. Now, the morphine passes from the blood into the stomach by osmosis and by excretion, and, by the principle of osmosis, more morphine will be excreted if it is decomposed as soon as it passes into the stomach. Reasoning on this principle, we would expect that repeated small doses of potassium permanganate by the stomach would be of use in cases where the morphine has been absorbed into the system. This is rendered more probable by the fact that morphine, as a rule, is a slow-acting poison.

The Properties of a True Antipyretic.

B. W. Richardson (*Asclepiad*) says the substance to be used medicinally for the purpose of reducing temperature must have three qualities: (1) It must be antiseptic; (2) it must be volatile; (3) it must have the slightest solubility in blood. If it be not antiseptic it is negative in its action as a suppressor of heat. If it be not volatile it accumulates in the blood and tissues, acts then as a foreign body toxic in its nature, and itself causes secondary symptoms which are mischievous and unnecessary, taxing active eliminative organs, like the kidneys, to an undue degree. If it be very soluble in the blood and in the fluids of the tissues, it is the more objectionable on account of its fixation and slow elimination. The value of ammonia as a medicine rests largely on its possession of the three qualities that have been enumerated. It is a splendid antiseptic and it is volatile, but it is too soluble and too powerful a solvent. Given in sufficient doses to check the animal fire, it dissolves the red corpuscles, prevents the free absorption of oxygen from that effect, and by its presence in the blood also tends to prevent oxidation. Chloroform is a splendid antiseptic; it is volatile and, feebly soluble in blood, it does not produce any fixed toxic symptoms nor tax the eliminatory organs unless it be pushed to anæsthesia. The author has used it for over forty years as an antipyretic, and with much satisfaction, but the difficulties of its correct administration have stood much in the way. Hydrate of chloral is more manageable. It is an antiseptic; it turns into chloroform and sodium formate in the body, so that it is both volatile and eliminative, and unless it is pushed too far it is not toxic. In his first observations made on it, immediately after Liebreich's discovery of its narcotic effects, Richardson discovered its remarkable power of reducing animal temperature, and pointed out that when it kills by a large dose the mode of death is by reduction of the body temperature. Since then he has employed it regularly as an antipyretic, and the results he has witnessed from its use surpass all others. "It is without doubt," concludes the author, "when correctly administered, an admirable remedy for pyrexia, and in enteric fever it is, I believe, the best."—*Brit. Med. Jour.*

Vaccination.

Before the introduction of vaccination the mortality in Austria from small pox was 62 per 100,000; in Prussia, 49. Since the introduction of vaccination the mortality has been 2 cases in 700,000. In Germany were revaccination is compulsory, the death-rate is 1 patient in every 1,200,000.

Rest in Heart Affections.

Lauder Brunton, the eminent English therapeutist, recommends absolute rest in cases of advanced mitral disease. Rest enables the circulation to recover its balance, the excessive accumulation of blood in the veins giving place to the proper distribution of the blood between the brain and the arteries; the dropsical effusion and general venous engorgement of the various organs, including the viscera, thus disappears. The change from absolute rest in a horizontal position to the vertical position, with gentle exercise, must be very gradual indeed. Massage and manual Swedish movements are of the greatest value in making the transition, and also in aiding the re-establishment of the normal circulation. The timely enforcement of rest in cases of this sort may save the beginning of the valvular malady of the heart, and thus by judicious management restore the patient to a condition of comparative health and comfort. We have found hot and cold sponging of the surface of the body of great value in the restoration of the normal balance of the circulation.

Dr. Brunton very properly calls attention to the danger of enforcing the rest cure too vigorously in cases of anæmic girls who, by too prolonged rest, are likely to fall into a state of exhaustion in which the heart will receive greater injury than from gentle exercise.—*Mod. Med.*

Early Diagnosis of Phthisis.

Bernheim, of Paris, presented at the congress at Rome (*Bull. Med.*) a paper in which he called attention to the importance of examination of the spleen and the lymphatic glands in cases of suspected tuberculosis. According to this observer, the spleen is always enlarged in cases of tuberculosis, even in the early stages of the disease. This is a new diagnostic point in tuberculosis, and one which should be carefully studied. As a bacteriological test it is exceedingly valuable in advanced cases, and is also applicable when the disease is in an incipient stage.—*Mod. Med.*

Digestibility of Sterilized Milk.

Bendix (*Jahrbuch fur Kinderheilkunde*, Vol. xxxviii, Part iv) has made researches upon sound and sick children as to the digestibility of both sterilized and non-sterilized milk. He concludes:

1. That in healthy children there is no difference as to the digestibility of the two milks.

2. In sick children the sterilized is digested just as well as the unsterilized, notwithstanding the fact that the absorption of fat and nitrogen is so much reduced in such children.

3. The taste and smell of milk, while they may be changed by sterilization, are not materially so, and sterilized milk is readily taken by children.

4. He has never seen the health of children badly affected by the use of sterilized milk. On the other hand, they eat well, grow, and their stools are normal, and they never have vomiting.

5. The transmission of severe diseases from animals to men is prevented by the sterilization of milk.

6. Sterilization is much preferable to Pasteurization, and heating the milk to 212° F., while it does not hinder its digestion, absolutely kills all bacteria and spores.

Periods of Isolation for Contagious Diseases of Childhood.

In the course of a report on this subject Olliver (*Gaz. Med. de Strasburg*) makes the following rules:

For scarlatina, variola, varioloid and diphtheria, the period of isolation, before the child is allowed to return to school, should be forty days, counting from the first day of invasion.

For measles and varicella, sixteen days will be sufficient.

For pertussis, isolation should be prolonged to three weeks after complete cessation of the characteristic kinks.

For mumps, ten days after the disappearance of the local symptoms.

Nasal, buccal and pharyngeal irrigations with antiseptic solutions should be employed, and soap bath and rubbing of the entire surface and scalp should be a necessary preparation before returning to school.—*Amer. Jour. of the Med. Sci.*

Pilocarpin in Diphtheria.

At the seventh general meeting of Polish physicians and naturalists at Lvov, Dr. Kowalski read a paper (*Medycyna*) wherein he recommends pilocarpin as the best remedy for diphtheria (which method he applied in 132 cases during the last fourteen years). The following formula is used by the author:

Pilocarpin muriatic.....	0.09 gram
Brandy.....	20 grams
Aquæ..	60 grams

M. D. S. A teaspoonful every two hours.

As adjuvants he prescribes: *a*, inhalations of a from 0.1 to 0.15 per mille solution of corrosive sublimate, to repeat every two or three hours; *b*, painting the throat with a 5 per cent. solution of carbolic acid, to repeat as frequently; *c*, wine in largish quantities; *d*, strengthening dietary.

Dr. Kowalski feels inclined to attribute the beneficial effects of pilocarpin to its inducing leucocytosis in diphtherial patients, which hypothesis seems to find some support in the results of the following experiments: He took eight healthy white rabbits (of equal weight) and inoculated them with equal amount (five divisions of a Pravaz syringeful) of pure glycerine broth culture of diphtheria microbes, after which four of the animals received each a hypodermic injection of 0.003 gram of hydrochlorate of pilocarpin, while the other four remained without the injection. It proved that in the former group there developed a distinct leucocytosis (from 12,000 to 20,000 leucocytes to 1 cub. mille of

blood), while in the control animals the proportion did not show any deviation from the standard.—*St. Louis Med. and Surg. Journal.*

Treatment of Insomnia.

The multiplication of sleep-producing drugs shows that the manufacturing pharmacists are trying to supply a demand made by physicians and a high-strung public. It is so much easier to give or take some pleasant hypnotic than it is to use natural methods that the latter course has been very much neglected.

At the Cumberland meeting of the State Society, Dr. E. N. Brush advocated the use of the common-sense methods and opposed the use of these drugs. Physical and nervous exhaustion are too common among the American people, and too many have learned or have been taught that such drugs as produce sleep are harmless, and resort to them without the physician's advice and too often with his advice. In the place of these Dr. Brush advocated attention to the skin, massage, baths and the use of easily digestible and nourishing food.

One method of producing sleep and quieting excitement which was not mentioned was the modern novel. Diversion is the principle of many forms of treatment, and if by a good, harmless, but interesting novel the attention can be distracted, the good is incalculable. Those who do not feel like reading may have a good reader, which at the present day is scarce enough. Indeed, in some forms of illness a good story-teller is a very good prescription. As Dr. Brush has said, natural methods are too often neglected. This is because they are sometimes more trouble than the mere swallowing of some small dose, or they are so simple that the patient can understand them. Familiarity belittles almost anything, and advice without a prescription in the present day is too often considered worthless by those who love to be dosed. Some humorous writer has collected the numerous remedies recommended by friends and others for sleeplessness, and they are varied and contradictory.

These natural methods are important and should never be neglected, even if some harmless prescription or placebo has to be given at the same time.—*Maryland Med. Jour.*

Papain for Tapeworm.

Roberts Bartholow (*Med. News*) reports a case in which, after failure of the usual remedies for tapeworm, a parasite twenty-five feet in length became dislodged and was passed after the use of papain, in ten-grain doses, three times a day after meals. The worm had not undergone solution, but Bartholow thinks the drug had exerted a toxic influence upon it.

Use and Misuse of Bicarbonate of Soda.

Dr. Rosenbach (*Cent. f. d. Med.*) claims that the bicarbonate of soda is prescribed by far too often to neutralize excess of acid in the stomach. It is, except in extreme cases, difficult to determine whether the excess of acid is abnormal. To determine whether the excess of acid is the real cause of stomachic disturbances, a careful consideration of the patient's occupation, his general condition, feces, nutrition, the consistence of the stool, etc., is necessary. In too rapid eating there is prone to be a faulty relation of motor functionability and production of acid. Formation of organic acids—fatty or lactic acid—may be a cause. Thirdly and most frequently, the dyspepsia is due to pure hyperesthesia of the organ. On account of its sedative action the bicarbonate is often misused and in too large doses; not more than a good-sized pinch should be taken at one time. Frequently a piece of dry bread or biscuit will suffice to absorb the excessive acid.

Phenacetine for Enuresis.

Holladay (*Va. Med. Monthly*) has found this drug excellent in cases of enuresis in children, five grains at bedtime, and in the troublesome, too frequent micturition where there is enlarged prostate, especially where cystitis is present, the urine being made acid. In such cases he gives a large dose, as much as twenty grains, at bedtime, with the happy result that the patient sleeps better and does not have to arise so often during the night. He has never had any bad effects that could be ascribed to the drug, and thinks, from all the reports of it that are noticed and from his own experience, that it is the safest of the coal-tar antifebrifuge products that are at present in use.

For Continued Syphilis.

Dr. Joseph Jones (*Louisville Med. Monthly*) gives the following formula:

Red iodide of mercury	grs. iv
Iodide of potassium	ʒ iv
Tincture of iodine	ʒ ij
Distilled water	q. s. ad ʒ viij

Sig.: A teaspoonful in a wineglass of water three times a day, one hour after each meal.

Cascara in Rheumatism.

In the *Louisville Medical Monthly* Dr. Cannon reports sixteen cases of rheumatism treated by fluid cascara sagrada aromatic in teaspoonful doses every three hours until the bowels moved freely, then fifteen drops every two hours. All recovered in a few days, and he declares: "Any one who tries this remedy in rheumatism cannot help but be satisfied with the quick results obtained."

Old Age and the Death-Rate.

Only 906 persons in a million die from senility, while 1,200 succumb to gout, 18,400 to measles, 27,000 to apoplexy, 7,000 to erysipelas, 7,500 to consumption, 48,000 to scarlet fever, 25,000 to whooping-cough, 30,000 to typhoid and typhus and 7,000 to rheumatism. The averages vary according to locality, but these are deemed pretty accurate as regards the population of the globe as a whole.—*Med. Age.*

SURGERY.

The Janet Method in Urethritis.

The pathogenesis of the gonococcus has been fully established, but as yet all specific remedies recommended for gonorrhœa have proved futile. The best treatment now, as before, is the prophylactic. Ricord's observation, "Une chaude pisse commence, Dieu le sait, quand elle finira," is equally applicable at the present day, notwithstanding the progress made in the pathology of gonorrhœa. At the genito-urinary clinic of Posner a routine treatment for gonorrhœa is the Janet method, which consists of irrigating the anterior urethra (in anterior urethritis) with many liters of a solution of permanganate of potash (1:100). The strength of the solution is gradually increased until a strength of 1 to 1,000 is reached. The solution is preferably warmed before being introduced. A simple contrivance enables the solution to escape continually after it has fully passed through the course of the anterior urethra. In the beginning it is advisable to irrigate twice daily, and as the strength of the solution is increased, once daily is considered sufficient. Janet's has yielded the better results at this clinic than all other methods of treatment. In urethritis posterior a catheter is carried beyond the compressor urethræ, so that the solution may reach the posterior urethra.—*Occidental Med. Times.*

Deaths from Cycling.

In a recent session of the Paris Academy of Medicine, Petit reported three deaths occurring suddenly during the use of the bicycle. The first case was that of a man sixty-five years of age who had begun to ride four weeks previously. He died in the arms of his teacher as he was about to get off his wheel. The second case was that of a physician, aged forty-eight years, who for the sake of reducing a corpulence which had come on after typhoid fever took to cycling. Without previously having complained of heart symptoms he was one day, while on his wheel, suddenly taken with dyspnœa and a severe pain in the heart region. He stopped, sat down on a bench and died in a few moments. The third case was that of an athlete, aged forty years, who died suddenly on the street while cycling.—*Deutsche med. Woch.*

Technique of Making Urethral Injections.

Guiard (*Annales des Maladies des Organes Genito-Urinaire*) gives the results of his investigations concerning the urethra and its medication. The capacity of the urethra had been stated by Jarnin and Leprevoct to be from 5 to 8 grams, therefore it was held that a urethral syringe should not hold more than 5 or 6 grams, equal to about 1½ drams. Later it was shown that posterior urethritis, particularly late in the disease, was far more frequent than formerly supposed. The author by experimenting on the living subject found that the urethra would always hold 8 to 10 grams (2 to 2½ fluid drams), and more often 12 to 15 grams, and sometimes 16 to 17. As the patient could tell when the sphincter was forced, this was avoided. These deep injections are only called for when definite symptoms have already demonstrated that the posterior region of the urethra is already affected.

In order to administer these deep injections, the author uses a syringe of 20 grams (5 drams) capacity. When it is desired to overcome the sphincter gentle pressure is made, when the liquid will enter. In an experience of ten years he has never had any accidents, and only encountered one case in which the sphincter would not relax. It is better to give the injections when the patient is lying down than when he is standing up. The requirements of an effective injection is that it shall reach all the diseased parts. To do this a syringe of 20 grams (5 fluid drams) capacity should be used, and the injection of its entire contents, if carefully done, is easy and causes no inconvenience.

BACTERIOLOGY.

Green Pus and the Bacillus Pyocyaneus.

Schimmelbusch (*Cent. f. Gyn.*) writes regarding the pathological significance of green pus and the bacillus pyocyaneus. Green and blue pus is the result of the bacillus pyocyaneus. Through its growth in the secretion of a wound it causes a green coloring matter—pyocyanin—and a characteristic sweetish, musty odor, which may be slight or most offensive. This bacillus produces not only green and blue coloring matter, but also, as may be seen in a single wound, yellow and brown. The richest shade or shades of these four colors may be seen. The amount of irritation produced in a wound depends upon the amount of air present—*i.e.*, oxygen—whether there is a favorable culture medium for the bacillus and the conditions or quality of the bacillus itself. He then answers the interesting question why this bacillus appears in clinics and hospitals and why it always appears in wounds. The wound is not infected through the atmosphere or dressings or by the hands and instruments of the physician, but the bacillus is normally found on the skin as a saprocyte. It has a predilection for particular parts of the body, as the axilla, inguinal regions, anus, etc., and therefore most frequently infects wounds near these parts. Is the bacillus pyocyaneus pathogenic? From experimentation upon animals and as far as observation upon man has gone, this organism is locally and generally virulent, but the virulence depends upon the character of invasion.

The Bacillus.

He that despiseth small things shall fall by little and little.—Loj the bacillus.

The bacillus is paradox itself: it is at one and the same time the weakest, minutest and

yet the mightiest of created beings. Individually he is the sixteen-millionth part of weakness and nothingness; collectively he is the consummation of destructive power. All life succumbs to him. The bacillus was born nobody knows how nor when, but it is evident that he did not "die a-bornin'," nor could he help his birth; but that he was born before man his vegetable origin testifies. He was born educated and needs no training. He labors every part of every second in the day and knows not how to neglect a duty. He is neither Republican, Democrat nor Populist, but a simon-pure nihilist. All things have an end except the bacillus, and he has two ends, and each end makes two more ends; each end and every other part of him is productive. A single bacillus in a single day will have 16,000,000 descendants, and each descendant proceeds with due order and regularity to beget 16,000,000 more, so that 16,000,000 multiplied by 16,000,000 every hour in the day will barely give a commensurate idea of his productive powers. The bacillus in breeding is a good deal like the negro's conception of a mule kicking, that is, "mule don't kick accordin' to no rule;" the bacillus multiplies according to no rule, but that he is the greatest multiplier in the world no man can doubt. Arithmetic don't contain enough numbers to outcount him. His relationship is extensive; he is at the same time father and mother, sister, brother, uncle, aunt, cousins, grandfather and grandmother. It has never been determined whether he is his own mother-in-law or not. He is noble by birth and surroundings, and only lives on highly organized bodies. He feeds upon emperors, czars, kings, princes, even politicians and all living kind. His residence is the grandest product of God; crude substances will not catch him. He requires fresh air at one time, at another not, but always moisture; he stands temperature well, thrives between 86° and 104° F.; but when it comes to cold he can give the famous brass monkey a thousand points and discount him. You may freeze him 200° below zero and he will only hibernate; he is like the grain of corn wrapped up with the body of a mummy for several hundred years, dormant and unproductive—he only needs heat, light and moisture to fill him with active vigor. You can find him only where there is plenty of company; he abhors a desert, detests the open sea, altitude gives him a weak heart, hence he is never found on high mountains. He is found in earth, air and water, and like a good Christian cannot thrive in hades. He is distributed universally, individually and collectively; killed by the sigh of a flea, he himself kills the strongest product of God. He is more destructive to human life than wars, famine, floods, earthquakes, railway trains and threshing-machines multiplied many times over. He is greater than the greatest because he has affected and controlled all generations of animal life; his activity is boundless, his value is known only to God, his capacity for evil has never been computed. One of his species alone (the tubercle bacillus) kills 142,857 persons out of every million dying from all causes, not to mention the hundreds of thousands of deaths produced by his near relatives. For man a word is sufficient, but the bacillus wants the earth; not only man but all animal life is demanded; man's creation was the bacillus' opportunity and he embraced it. He is a rod and comes very near being the chastening rod of God.

He is the idol of death, the boon companion of misery.

He is the mighty, dire remorseless, unceasing and hideous Nemesis of man's ignorance.

Ay, a mighty remorseless curse on man then was hurled—
A hideous horror, killing scourge, Death's enigma to the world.

—*Railway Surgeon.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM DECEMBER 16, 1894, TO DECEMBER 22, 1894.

Leave of absence for one month is granted First Lieutenant A. N. Stark, Assistant Surgeon, to take effect upon his return to Fort Sam Houston, Texas.

Captain James D. Glennan, Assistant Surgeon, is relieved from duty at Fort Sill, Oklahoma Territory, and ordered to Fort Snelling Minnesota, for duty at that post.

Captain Edward R. Morris, Assistant Surgeon, on the arrival of Captain Paul Clendenin, Assistant Surgeon, at Fort Warren, Massachusetts, will be relieved from duty at that post and will report for duty at Fort Spokane, Washington.

PROMOTIONS.

To be Assistant Surgeons with the rank of Captain, after five years' service, in conformity with act of June 23, 1874: First Lieutenant Charles Willcox, Assistant Surgeon, October 29, 1894; First Lieutenant Harlan E. McVay, Assistant Surgeon, October 29, 1894; First Lieutenant Euclid B. Frick, Assistant Surgeon, October 29, 1894.

THE
MEDICAL AND SURGICAL REPORTER.

No. 1975. JANUARY 12, 1895. VOL. LXXII—No. 2

ORIGINAL ARTICLES.

VARICES OF THE ŒSOPHAGUS.*

DR. PAUL FRIEDRICH.†

The œsophageal veins are divided into three groups. 1. Those tributary to the superior vena cava by way of the inferior thyroid, pericardiac, posterior mediastinal, intercostal and the superior diaphragmatic through the azygos and hemiazygos veins or occasionally directly into the trunk of the vena cava. The branches of the inferior thyroid at the level of the larynx form numerous anastomoses with one another and with branches of the superior thyroid. 2. The tributaries to the portal system send their blood through the left coronary vein of the stomach. 3. A few insignificant and irregular branches communicate with the inferior vena cava through the inferior diaphragmatic veins.

All the veins form a thick network of fine radicles, far surpassing the arterial anastomoses. The veins are most numerous in the lower part of the œsophagus. There is an internal plexus in the submucosa and an external or pericœsophageal plexus which form numerous anastomoses through the muscular coat. The pericœsophageal veins are grouped into anterior and posterior bundles, which pass to the cardiac orifice with many connecting twigs.

Besides the connections between the general and the portal circulations by way of the œsophageal veins, there are two other means of establishing collateral circulation in cases of portal obstruction—the system of Retzius, consisting in the venous radicles from the abdominal wall that communicate with the mesenteric veins and flow into the inferior vena cava or one of its branches, and, secondly, the hemorrhoidal veins that communicate with the inferior mesenteric and the internal pudic.

[The author omits the communication through the veins of the round ligament of the liver.]

It has long been recognized that varicose enlargement of the œsophageal veins may take place, and almost always in conjunction with some disease of the liver that by contraction interferes with the flow of blood in the portal system. In the reported cases no cause is assigned for the enlargement of the œsophageal veins, while those of the system of Retzius and the hemorrhoidal veins are not implicated—at least, no mention is made of the veins of Retzius, while Charcot states that the hemorrhoidal veins are never enlarged in hepatic cirrhosis, but are constantly found contracted and impenetrable (undurchgängig). [It would seem that the author must have a definite series in mind.]

In 1858 Faurel and Diberder reported two cases of varix of the œsophagus

* Condensed translation by A. L. Benedict, A.M., M.D., Lecturer on Digestive Diseases, Dental Department University of Buffalo.

†Assistant at the District Polyclinic at Leipsic.

that ended fatally on account of hemorrhage. Bentz in 1884 could collect only sixteen cases out of the entire literature of the subject, to which he added three of his own observation. Sundberg in 1886 published another case.

The obstruction in the portal circulation is referred to hepatic cirrhosis in most cases. Blume found that while in a few cases the interference with the circulation was slight, in most instances it was marked. From the formation of collateral blood-paths, the obstruction was postponed and œdema and ascites were generally wanting or occurred late. Besides hepatic cirrhosis, syphilis of the liver, all contracting processes and interstitial connective-tissue overgrowth, Zenkler considers senile atrophy as prominent in the etiology of œsophageal varices. [Evidently cirrhosis is used in a narrower sense than is customary in this country.] Yet varices occur in only 21 per cent. of his cases of chronic atrophy of the liver and in only 5½ per cent. of those of hepatic cirrhosis. The ages of his patients varied from thirty-nine to seventy-one. Two further cases are of interest, those of von Frerichs and von Sundberg, in which a thrombus in the portal vein led to the formation of varices.

The course of the varicose veins, as Blume found by injecting the coronary vein of the stomach, is as follows. In the neighborhood of the cardia, a few centimeters above or below, several veins rise from the deep tissues under the mucous membrane and ascend perpendicularly in the œsophagus, usually in two or three cords. The varices are usually found in the lower third of the œsophagus. Blume holds that cases depending on general venous stasis progress equally in the whole length of the œsophagus, while those depending on the back flow of blood from the portal system begin below and gradually extend upward. The first chart of the Kast-Rumpel atlas of pathological anatomy affords an example of œsophageal phlebectasia depending on general venous stasis. Klebs pictures varices projecting on the surface of the lower part of the œsophagus and appearing as long blue ridges thickened into knots here and there and for the most part covered by a very thin layer of tissue.

The principal symptom, or rather usually the only clinical symptom, of the disease is hemorrhage. Klebs says that injuries to the varices can bring on dangerous hemorrhages, especially when they pass over the rim of the cardia and come in contact with the gastric juice. Several times section demonstrated the exact place of injury to the vein. At other times nothing noteworthy was found; the examination, however, was made not for extravasations of blood, but always for real hemorrhage and less of substance.

The present case was that of a girl aged six, healthy till two years and a half before death. At that time frequent headaches and occasional pains in the body set in and the child became pale and weak. There was no digestive disturbance except frequent diarrhœa. Vomiting never occurred. In the spring of 1892 repeated hæmatemesis set in with pains and diarrhœa which improved under treatment with opium and ice. In the summer of 1893 the child again came under medical care on account of indefinite distress in the abdomen. No further details are known till October 14, 1893, when the child was brought to the Polyclinic in a condition of profound anæmia, with the statement that she had had a violent hemorrhage the evening previous. Examination of the chest, especially of the heart, revealed nothing abnormal. The abdomen was somewhat enlarged, bloated, but in no place painful or tender. The diagnosis was made of gastric ulcer and opium and ice were prescribed, followed three days later with pills of silver nitrate. Hæmatemesis occurred again on October 19th in greater amount than before. The vomited matter was bright red mixed with dark clots. On the next day the hemorrhage recurred with bloody coffee-ground stools. The pulse was small and very weak. The temperature rose at noon to 39° C. The child lay in such a condition that the propriety of saline injections was considered. In the evening the temperature had sunk to 37.6° C. and the pulse, though extremely weak, was stronger. Its frequency was 160. The next day the patient was in a condition of extreme weakness and quite apathetic, complaining only of thirst. On October 22d the pulse was 156, sinking on the following day to 132, and thereafter ranging from 120 to 130. Nourishment was maintained with iced milk and the only drug used was opium. On October 30th, ten days after the

hemorrhage, marked restlessness ensued, manifested by convulsive movements of the extremities and especially of the facial muscles, while speech became impossible and much gnashing of the teeth was audible. These symptoms increased and in addition choking on attempting to drink, smacking and shouting sounds occurred. Thus in a few days a chorea of high grade developed. The disease did not continue long at this pitch, and from November 10th a considerable retrogression was evident. Speech returned first, while the choreic movements of the extremities continued for a time. The last trace had disappeared by November 18th; that is, the disease had spent itself in three weeks.

From November 9th a systolic bruit was audible at the apex and the base of the heart as well as over the larger cervical vessels. About the same time enlargement of the heart, both to the right and the left, was demonstrable, features which left one in doubt as to whether they should be ascribed to marked anæmia or to chorea. The vomiting had stopped on October 20th, and the child gradually recovered from the profound anæmia, so that about the middle of December she could leave her bed for an hour at a time. The diet was regulated most carefully. Till the beginning of December nourishment consisted only of milk and infant's meal; then it was extended to eggs, tender meat and green vegetables. All this time there were no gastric symptoms; the appetite was good; only occasionally was complaint made of a slight oppression in the region of the stomach and at times the abdomen was slightly distended but without showing any fluctuation. At 3 P.M., December 26, 1893, violent hæmatemesis set in. Shortly before the patient complained of distress and pain in the stomach. About three-quarters of a liter of bloody gastric contents were vomited, having an acid reaction.

An error in diet was responsible, the child having taken a piece of potato against her mother's will. Vomiting returned the next morning and on January 9, 1894, the child died, apparently exsanguinated. The pulse had risen to 160 and so remained till death. There was no fever.

On autopsy the next day the heart was found greatly dilated, especially in the ventricles. The heart muscle was lax and of a yellowish-red tint. Through the endocardium shone intensely yellow flakes and stripes. The free edge of the mitral valve was slightly thickened; at the line of closure of the outer leaflet there was a soft reddish-gray translucent deposit the size of a cherry-pit. The foramen ovale was closed. There was nothing significant about the lungs, nor was there any pleural or pericardial effusion. In the abdomen was about 400 c.c. of milky, turbid fluid containing 0.54 per cent. of fat. The peritoneum was free, the lymph-nodes were not enlarged. The liver, spleen and kidneys were fatty degenerated, conditions that, with the general adipose deposit that was especially marked in the abdominal parietes and the mesentery, were to be ascribed to the anæmia. The spleen was very large. A careful dissection of the portal vein, thoracic duct and vena azygos was negative, and the single positive finding was the existence of marked varices in the œsophagus. I have prepared a water-color to represent the clinical picture. The veins ran mostly in two cords, of which the larger one, on the right, consisted of dark blue twisted and knotty veins about the size of a lead pencil. These veins took their origin from two trunks that, rising under the mucous membrane through the muscular coat, about two centimeters below the cardia, came together like the prongs of a fork and ascended in the œsophagus perpendicularly, giving off a lateral branch at the point of union. The latter also rose perpendicularly, but without marked enlargements, and was visible through the mucous membrane as a more diffuse, blue-black streak. Between the two main trunks were numerous anastomoses that were especially numerous above, and there the mucous membrane took on a diffuse dark redness. At the level of the cricoid the injection ceased and the normal pallor of the mucous membrane took its place. No lesion was discoverable in the mucous membrane which could be considered as the source of hemorrhage. In the loose connective tissue between the trachea and œsophagus there was visible a varicose venous cord as thick as a pencil and about six centimeters long. The gastric mucosa was exceptionally pale. There was no varicosity on the outside of the stomach nor elsewhere in the portal system.

The diagnosis of gastric ulcer, depending on the symptoms, was made with some hesitancy, since previous experience is against its occurrence under the age of ten. Ewald and Hennoch have recognized gastric ulcer in children, the former's two cases lacking only hæmatemesis to complete the typical picture. Brinton in 226 dissections of gastric ulcer found it twice in children under ten.

After the occurrence of hemorrhage in the present case in the fourth year, it occurred a year and a half later with renewed violence in spite of every treatment. Previous medication with silver nitrate and after the last hemorrhage with liquor ferri sesquichloridi was abandoned as useless; the only rational treatment seemed to be the strictest diet. How important this was and how urgently it was indicated without our knowledge the section revealed, as well as the fact that error in diet even to the extent of swallowing a piece of potato proved to be the direct cause of fatal hemorrhage through laceration of a vein. This conclusion is not weakened by the failure to find the lesion, since death followed on the thirteenth day after the last hemorrhage.

The distention of the abdomen that is occasionally mentioned in the history found its explanation at the necropsy in a slight ascites of milky consistency. [Without the positive statement that the abdomen was dull, at least in the dependent portions and in the explicit absence of fluctuation, one would naturally attribute the enlargement to tympanites.] Such an exudate, according to Quincke and Senator, arises either through mixture of chyle or from fatty detritus. Through an unfortunate accident microscopical examination, the principal test, was prevented. If we had to deal with an ascites adiposus, as Senator has designated it, the microscopical examination would have shown cellular elements. According to previous experience, the fact that 0.54 per cent. of the fluid consisted of fat does not contribute to the certainty of diagnosis. The rich fatty degeneration of organs and the fatty infiltration supports the conjecture that the fluid was an ascites adiposus. Klebs has mentioned a case in which he showed such an ascites to have arisen from the fatty degeneration of the mesentery. That this ascites could have led to stasis and consequently to the formation of œsophageal varices is disproved by its small quantity, and it is to be considered as an accident, not an etiological factor.

Highly interesting, though not properly belonging in this discussion, is the onset of chorea immediately after the violent hemorrhages. Although there is nothing in the history about an earlier choreic condition which might have been exacerbated, the present choreic seizure certainly affords an example of the dependence of the disease on anæmia. Its rapid onset and speedy recession—the entire duration of the attack being scarcely three weeks—show the causal relation of the hemorrhages. Similar cases are few in medical literature. Litten's work on the etiology of chorea mentions the frequent occurrence of chorea following anæmia [not due to hemorrhage]. Stephen MacKenzie cites 439 cases, in about 20 per cent. of which a high grade of anæmia existed. The disease is also common after pregnancy, disturbances of menstruation and during childhood, especially in the female sex, and these facts lead Joffroy to term it "nervose cérébrospinale d'évolution." Litten observed in a primipara in the eighth month, immediately after venesection, choreic movements in the face and arms, spreading to the whole body after a repetition of the venesection. After delivery which followed rupture of the membranes the patient died of exhaustion. A similar case of chorea set in on the sixth day after violent nose-bleed and also ended fatally. [The similarity is not very evident. The former case with repeated venesection and premature labor following rupture of the membranes would suggest uræmic eclampsia.]

To return to the findings of the autopsy. The case must be included with some of Rokitansky's and Eberth's as presenting no appreciable obstruction to the circulation. Eberth has indeed considered gastric catarrh of twelve years' duration in a man of forty as an etiological factor in the production of œsophageal varices, and Duret has advanced the hypothesis that normal respiration could bring on an ectasia. During expiration there is increased pressure in the portal system, which suddenly sinks in inspiration. The vessels dilate and the suction of the enlarged thorax causes a rapid determination of blood in the direction of least resistance. Now as soon as the liver affords an

obstacle to the flow, the connection of the portal vein with the principal veins of the thorax through the œsophageal veins affords a way around the portal system, and the ever-recurring distention of the veins will finally bring about a permanent ectasia. But if an everlastingly (unendlich) frequent condition [chronic gastric catarrh] and a normal one [respiration] tend to produce this dilatation, why are not varices of the œsophagus more frequently observed?

The youth of the patient has no decided bearing on the etiology of the affection. I pass over the question whether we must assume a congenital anomaly of the œsophageal veins or a diminished resistance on the part of the vascular walls which gradually allowed the ectasia to develop under circumstances of impeded circulation somewhere, and I would report the case only as a casuistic example of a strange abnormality of the veins of the œsophagus.

GASTRO-ENTERITIS OF CHILDHOOD.*

CHARLES CARY, M.D., BUFFALO, N. Y.

Night before last there was brought to the hospital a little Arabian boy who exhibits so many peculiarities that I have concluded to present his case.

The mother being unable to speak English, the history which we get is vague. The child was weaned two months after birth, and has been reared on the bottle for the remaining three months of its life.

It is much emaciated and the skin is wrinkled like that of an old, old man. The baby is pale, dull, inactive, but it has no rise of temperature. The abdomen is very full; the line of separation between the stomach and the colon can almost be seen through the skin. The stomach and intestine, being thus distended, are tympanitic on percussion. There is very little tenderness of the abdomen, otherwise the child would cry loudly when I percuss and palpate. Yesterday the evacuations were very abundant in number and bulk. In character they were watery and greenish, containing considerable undigested milk. The mother gave us to understand that the child had been sick five or six days, with frequent watery stools and vomiting. This is a condition that will be encountered very often, and will be seen much more frequently among the ignorant than the better classes. It is a common condition attending the bottle-fed child. It is a cause of death for about half of all infants. One-third of all persons born die before completing their second summer. On account of acute illness, peritonitis, shortly after the birth of the baby the mother was unable to nurse it, and she shows an anxiety about the infant which is truly pathetic.

Parents frequently have begged me to do something for a child, and on asking a few questions I have found the trouble to be with the diet. For example, in one case I was told that the child was extremely fond of pickles and would eat little else. Errors in diet often do not suggest themselves to mothers as the cause of the illness of children. The food of breast-fed children enters the stomach with practically no access to the air. In artificial feeding, however, the food is frequently contaminated with atmospheric bacteria, and catarrhal enteritis follows from the irritating quality of the food. As a rule, there is not merely an enteritis, but a similar inflammation extending throughout the entire gastro-intestinal tract. We are not able to gain any definite information as to what this child has been fed. It may have been reared on sugar and water, or on potato pap, or on solid food, but the probability is that the nutriment has not been appropriate to the delicate condition of the child's digestive organs. Only a few recurrences of the diarrhœa could be tolerated in the present weak state of the child, and the outlook in any such case depends upon the reserve of vital strength.

The first point of treatment is to clear out any accumulation of irritating sub-

* A clinical lecture at Buffalo General Hospital.

stances in the alimentary tract. It is the common practice and, I think, a very good practice, to begin the treatment of any such case with a dose of castor oil. A good big teaspoonful would be the proper dose for a child of this age. Castor oil is a safe remedy even in full doses, any excess being carried through the bowel, but we must bear in mind that too liberal use will cause griping. It is, on the whole, much better to give a dose which will assure the thorough clearing out of the intestine than to allow any chance of delay. In addition to the cathartic treatment, it is well to wash out any mucus that may be in the large intestine by copious enemata of water about the temperature of the body, unless there is some fever, when the water may be a little cooler. Boric acid is often added to the water, to make a saturated solution. Some, even with infants of this age, begin their treatment with lavage of the stomach. Those who have used it are very warm in their praise of this means of treatment, but personally I have never used it in so young a child as this. The stomach tube used in such cases is usually a catheter. It seems to me that the washings can be conducted by the natural processes, for such children, as a rule, are very thirsty, particularly if they have any degree of diarrhœa, and they will take almost as much water as one will give them. They will usually take the water with greater avidity if it is sweetened a little or if it is flavored with some aromatic oil which in itself is a good antiseptic and carminative. Vomiting, also, is not uncommon, and thus the stomach can be washed out quite thoroughly. I would not, however, condemn lavage of the stomach even in infants.

After clearing out the stomach and bowels, the next consideration is what to feed the child. If you see the case at the beginning of an acute attack, it is better to suspend all nutrition for twenty-four hours, as the child can much better stand twenty-four hours of complete fasting than twenty-four or forty-eight hours of diarrhœa. By mild sedatives, a few drops of paregoric in water, the child can be satisfied and carried through the twenty-four hours. In less acute cases, however, nourishment is demanded. In the present case, for example, not knowing what the child has been taking, I should advise milk diluted two or three times with water. The food should be sterilized and the milk, by preference, peptonized. If after twenty-four hours the diarrhœa has not been checked, we shall know that a different treatment is needed. Under these circumstances we should suspend the milk and give beef-juice, which is always readily assimilated by infants. By beef-juice I mean the extract made by pressure from fresh raw beef, seasoned slightly and fed warm but uncooked. This is not suited to be a permanent article of diet, but is intended to tide over an emergency.

As a rule one will not need to resort to much medicinal treatment. This child, for instance, has no desire for food and will require no paregoric, which, of course, is not to be given unless demanded by the cravings of the child for food. If the case is still milder it is well to check the process of fermentation by the administration of certain drugs, and for a child of this age or a little older I know of no remedy better than bismuth subnitrate suspended in mucilage, perhaps with a little prepared chalk added. The common error in such treatment is in not giving large enough doses. Quarter or half grain doses for an infant like this would do no good whatever. A fair dose would be from three to seven and a half grains (0.20–0.50). The dose is practically unlimited, and while one does not want to fill the child's stomach with this insoluble salt, its action is local and largely mechanical, so that a minute dose is worthless. One must bear in mind that the main treatment is the care of the diet and that all medication is, to a degree, secondary. When, as in the present instance, it is necessary to feed before the digestion has recovered its proper tone in order to save the child from collapse, small quantities of beef-juice with from one to five drops of brandy, depending on the age, may be given at frequent intervals, even so often as every hour.

On account of the yeasty growth on this child's tongue I have prescribed calomel to be given for a short time only, in doses of $\frac{1}{10}$ grain (0.006) after each feeding. The child has also been taking peptonized milk diluted with an equal quantity of water, and under this treatment vomiting has ceased, diarrhœa has diminished very much and the child has been quiet and contented. I rather expect after twenty-four hours to be able to withdraw the

mercurial and to increase the nutriment by adding to each feeding a little beef-juice. I shall feel my way very carefully, for one or two upsettings of digestion might be enough to carry the child away.

Some might call this a cholera infantum. It is a little late in the season for that trouble; cholera also usually comes on with greater severity, with more copious serous stools, and very often the stools are so abundant and watery that the child dies in collapse within forty-eight hours. Commonly, however, the watery stools continue, but the patient either succumbs more slowly or gets well. This child has had its digestion impaired by long-continued errors in diet; there has been induced more of an enteric catarrh than of a cholera. Infantile cholera, though partaking of the nature of an infectious disease, has no specific bacterial cause. There are always bacteria in the intestinal evacuations; when digestion is disturbed the number increases and the variety may also increase, but I believe there has been no particular germ isolated as the cause of cholera infantum.

We must not overlook the child's skin, which is harsh, dry and leathery. This condition is very largely due to lack of nutrition. The child should daily receive a warm bath, taking care not to chill it. It is a common practice to nourish such children further by inunctions of cod-liver oil, which have the objection of causing a very disagreeable odor from the oil becoming rancid. This, however, is a secondary matter, and when children are in a condition of extreme weakness the little additional nourishment that can be introduced by the help of the inunctions may turn the balance favorably.

I think it is rather an open question whether this child will recover. It will depend largely on careful nursing, the supervision of the physician being a secondary matter after he has once laid down the law to be followed by the attendant.

(The child assimilated its food fairly well, but died a few days after, apparently from exhaustion. No autopsy was allowed.)

ERGOT IN THE HANDS OF IGNORANT MIDWIVES DURING LABOR.

G. M. DROSTE, M.D., GRAND RAPIDS, MICH.

On this subject, so far as I know, there is no literature to be found, but I do not think it at all new to any physician who has spent some years in active general practice.

It is alarming to see what suffering, disease and broken-down constitutions are brought about to the gentler sex through the ignorance of women who style themselves midwives. Having within the last few years had an extensive practice in obstetrics, I have come in contact with many different so-styled "practical," "qualified," "long-experienced," "no-doctor-necessary," and other well-named midwives. Thus I have had occasion to observe from their actions and work that while they pretend and, in some cases, honestly believe, to assist and shorten the sufferings of women who are about to become mothers, through their ignorance they do precisely the contrary. The following cases will bear me out in my statement:

CASE I.—Mrs. K.; Polish. Was called at noon July 4, 1888. On arrival I found a midwife in attendance. The husband, who called me, said that the midwife assured him everything was all right and that the child would be born as soon as labor pains would get strong enough. His patience, however, wore out after waiting a whole night and the next day until noon. The midwife did not seem to like the presence of a physician and treated me rather coldly. On making an examination I found a rather small child, with breech presentation, and very low down in the vulva. On asking the midwife how long the child had been in that position, she said, "Since twelve o'clock last night," thus making twelve

hours without any progress. Thinking it strange for the child to be in the one position for twelve hours when it seemed as though it might be born with one good labor pain, I made a more thorough examination. I found the body of the child in the vagina, the uterus high up, and the cervix uteri in a spasmodic condition locked around the neck of the child, holding the head within the womb. I asked the midwife if she had given any medicine and she replied, "Why, yes, doctor, right along since last night, even before the child came down." I called her into an adjoining room and asked her if she knew the reason why the child had not been born sooner. "Yes, doctor," she answered; "her pains are not strong enough." I explained to her the condition that was present and that it was due to giving too much medicine; but she did not seem to understand, nor did she seem to believe my words. I did not care to take the case from her, but advised her not to give any more ergot. On leaving the house I told the husband in case the child was not born in two hours to call me. The next day the husband came to my office to pay me for my call, and I learned that the child had been born one and a half hours after I had left. I also learned from him that the midwife had administered between two and three ounces of ergot within twelve hours during labor the preceding night.

Case II.—Mrs. B.; German; January 18, 1889. On arrival I found a midwife in attendance. On examination I found the cord presenting, the os uteri in spasmodic contraction; the cord very thick but no pulse in it. Midwife had administered ergot all night, but no good labor pains came. After discontinuing ergot for some hours, strong labor pains set in and the os dilated rapidly. The pulse not returning, I suspected the child was dead, the woman being a primipara, over thirty years old and with a contracted pelvis. I administered chloroform and with instruments delivered a dead child. Death was caused by the pressure of the head of child and the spasmodic contraction of os uteri upon the cord.

Case III—Mrs. S.; Polish woman; 1890. Midwife in attendance all night and all day. From what I could learn from her there had been a shoulder presentation at first, but, as she remarked, with the help of ergot and working with difficulty she managed to get an arm down, at which she kept pulling and working until she got tired out. I administered chloroform and delivered by the feet a dead child that by all appearance and according to the belief of the mother had been dead some hours, as she did not feel any life after the arm had come down.

Case IV.—Recently I was called to a Polish woman in labor. Midwife in attendance all night and had given ergot. On examination I found an arm presenting over and in front of the vertex. I administered chloroform, pushed the arm from the head over the face, applied forceps to the head and delivered. Mother and child both did well. I think that had the midwife succeeded in getting down the arm the child would have shared the same fate as the one referred to in Case III.

Case V.—Last winter, while treating Mrs. H. for la grippe, I was asked the cause of certain pains and weakness in the lower part of her back and loins. From answers to questions I remarked that she must have womb trouble, which, however, I would not be able to ascertain without examination. I told her to call at my office after she was well of la grippe, where upon examination I found a bilateral laceration of cervix and a ruptured perineum. The patient's history was as follows: Nine years ago she had had a difficult labor, a midwife attending her and giving her medicine. The child issuing with feet presenting, the midwife took hold of them and pulled forcibly, causing her great pain. She had immediately alarming hemorrhage. A physician was called, who examined and told her that she had sustained rupture of the womb. From that time on patient had always complained; had also had several miscarriages since, but none previous to that labor. I advised her to undergo two operations, to which she consented and was restored to health.

I could cite more cases if necessary. These five cases show sufficiently to what extent ergot is administered by unskilled individuals who out of a valuable remedy make an unfit and dangerous one. I believe that the drug is even too extensively used in the hands of many physicians, and I must admit that I myself have given it during my early years of practice in cases where I should hesitate

to do so now. I have used it less and less, until I now hardly ever have any use for it, and I find that I have better success and better results. Labor is a natural process and should be left in the hands of nature unless complicated. It is true that we very often can assist nature, but as soon as we interfere with a given law or process of nature we are apt to have bad results.

During labor ergot should not be given before the head of the child has passed through the os uteri; for if we do give it before dilatation is sufficient to admit the head we stand in danger of laceration of the cervix. Again, if the head of the child presses down upon a firm perineum which does not readily yield and we give ergot to produce strong labor pains, we stand in danger of laceration of the perineum.

The conditions where ergot is indicated during labor are:

1. Where the perineum is sufficiently softened and yielding, but the head of the child is very large and firm, so that the bones do not shape themselves to the outlet of the pelvis, and thus require extra strong labor pains to expel the head.

2. Again, where the head presses down upon the perineum and labor pains have stopped altogether or are too weak to have any effect.

3. And lastly, where labor has been very severe and tedious and the mother is in an exhausted condition and unwilling to suffer any longer.

The suffering and ill-health ergot produces when administered at the wrong time is not to be expressed by words. But it is not the drug that is at fault, but the individual that handles it. Why not, then, stop the hands that administer a drug which not only causes suffering to noble mothers, but brings even death to beings yet unborn?

This uncalled-for administration of ergot should be remedied, and the remedy to be used I leave open to discussion.

COMMUNICATIONS.

A MECHANISM OF INTUSSUSCEPTION—SPECIMENS ILLUSTRATING EACH STEP IN THE PROGRESS OF INFECTIVE APPENDICITIS.*

ROBERT T. MORRIS, M.D., NEW YORK CITY.

I. *Experiment.*—I shall expose the ileum of a rabbit, and it will then be observed that when it is touched with carbonate of sodium, contraction of the circular fibers of the bowel at the point touched will take place in from fifteen to thirty seconds. The longitudinal fibers of the bowel still carrying on peristaltic movement (a reversed peristalsis, by the way) will invaginate that portion of the bowel which is in a state of firm contraction. I do not know the exact value of this experiment except that it shows the mechanism of one form of intussusception. We know that certain ptomaines produce muscular spasm, and it is fair to assume that some cases of intussusception are due to a poisoning of the muscular fibers of the bowel as in the experiment. In post-mortem intussusception as I have watched it, there has been paralysis of the circular fibers of the bowel and an adjacent segment of bowel has dropped into the relaxed portion, almost the reverse of the mechanism demonstrated in this experiment.

APPENDICITIS SPECIMENS.

II. Appendicitis I believe to be an infective exudative inflammation of the appendix vermiformis, which follows the production of an infection atrium of any sort in the mucosa or in the peritoneal

*Read by invitation of the Board of Directors of the Philadelphia County Medical Society, November 28, 1894.

covering of the appendix. I believe that when the infection atrium has been produced bacteria at once enter the lymphoid structure and the cellular coats, and that then the stage of exudation begins and the tissues are compressed by the exudate. There is no doubt that in the majority of cases we have an exudate compression which is fatal or has a tendency to be fatal to the lymphoid and cellular coats, and the reason is because the lymphoid and connective tissues and mucosa are confined within a narrow tube of muscle and peritoneum. In the colon, when infection begins and exudation takes place, there is abundance of room for swelling, and the interstitial exudation does not lead to compression and anæmia. In the narrow appendix there is not room. The lymphoid tissue cannot do its work as a strainer of bacteria, and therefore the lymphoid, mucosa and connective tissue forming the inner tube are compressed to the point of strangulation in many cases. If not to the point of strangulation there is produced compression anæmia, which allows more rapid toxic destruction of the cells, and the toxines produced by the bacteria which have entered the infection atrium cause destruction of the cells before nuclein can be poured out and the leucocytes do their work. Thus there is frequently rapid destruction of the mucosa and lymphoid coats which should act as a protecting coat, but which is destroyed and becomes a prey to bacteria because it is under compression.

Very early proliferative endarteritis commences, and this occurs, as you will remember, in a small terminal artery, for practically the only arterial supply of the appendix is from a solitary terminal artery. If a branch of the artery becomes occluded, we have a round punch-hole slough formed at the point supplied by this branch. If more of the artery becomes obliterated, we frequently have complete gangrene of the appendix. Only a few hours are required for an obliterating endarteritis to become sufficiently marked to lead to destruction of all parts not supplied with blood by bacteria which are ready to pounce upon such parts. I think that usually in the very early stage of the infection we have a mixed infection. Streptococci are apt to be present, and these with other bacteria send the temperature up. The temperature from infection by streptococci or from mixed infection may be quite high, whereas when the infection is from the colon bacillus the temperature is apt to be not high, but about 100° to perhaps 101° during a most violent attack of infective appendicitis going on to death. This statement in regard to temperature I am almost prepared to make as a direct statement, but I shall wait for more observations before asserting that a high temperature indicates streptococci or mixed infection, and that a low temperature indicates a colon-bacillus infection. I am almost certain, however, that the toxine of the colon-bacillus does not send the temperature high.

Specimens.—The first is a normal appendix removed post mortem.

The next specimen shows the effect of exudation into the appendix a few hours after infection has taken place. The inner tube, composed of the lymphoid and connective tissue, is distinctly swollen.

In the third specimen we find a little rhexis, all the structures being infiltrated with blood.

There is a complete rhexis involving all the tissues in the fourth specimen, the fibers of all structures being separated by effused blood. In the case from which the specimen was removed the wound was very septic and no granulations formed for eight days. The patient then developed pneumonia of the right side, and after the pneumonia was well under way the appendix wound began to granulate and the patient recovered.

The fifth is another early specimen, in which there is a pin-hole puncture. In this case the appendicitis had lasted about forty-eight hours. The artery being obliterated at this point allowed a small pin-hole opening to form.

The sixth specimen, an inch of which has been removed, shows very nicely how the interstitial exudation causes the inner tube to be compressed by the outer tube.

Here is a specimen in which the bacteria have been confined to the appendix for several days and then suddenly passed through the mesappendix, and the patient developed acute septic peritonitis.

Here is another specimen in which a small punch-hole perforation formed and was immediately walled in by lymph. The appendix was quite free, except at the tip, where this mass of exudate held it.

This is a chronic ulcerating appendix.

After the acute stage of infection is passed the ulceration is apt to continue, because the appendix is a nook in which bacteria persist, and after the mucous membrane is destroyed the bacteria are apt to keep up a vigorous onslaught on the exposed tissues. These are the appendices that produce fatty concretions. I have found that concretions in the appendix are phosphatic, fecal, or fatty. Some of these concretions contain 50 per cent. of fat. It occurred to me that possibly a retrograde change in the lymphoid might account for it, and consequently I submitted the lymph coats of several appendices for examination. From normal appendices I obtained 8 per cent. of fat; from appendices with small ulcerated spots 19 per cent.; and from appendices with general ulceration of the mucous and lymphoid coats 26 per cent. This showed that the proportion of fat in chronic ulcerating appendices was very large, and if the products were confined in the tubes it is probable that these fatty concretions come from that source.

Before gangrene in the appendix has occurred we sometimes find gangrene of the mesappendix from thrombosis of the veins and obliterating endarteritis. Sometimes the appendix seems to receive enough nutrition from the cæcum to live a few hours longer than the mesappendix.

After infection has continued for some time—a few years—we frequently find excessive hypertrophy of the appendix. This specimen shows this hypertrophy in an appendix which was the seat of chronic ulceration. Most of the time this patient was without symptoms, but at times he was compelled to give up work. I found the appendix extremely tender on palpation, and learned that of late he had referred the pain to that region.

In some cases after destruction of the mucosa gradual wasting of the lymph coat takes place. This is shown in this mount of four transverse sections. In the first, the mucosa and submucosa are swollen with exudate. In the next, the mucous coat has disappeared and the lymphoid has almost disappeared. In the next, nothing but the muscular and peritoneal coat remain, and in the last there is no lumen and only a little remnant of the muscular and peritoneal coats.

In cases in which the terminal artery is involved quickly in proliferating endarteritis the entire appendix may become gangrenous. Here is an appendix which became completely gangrenous in thirty-six hours. No portion of this appendix remained alive, and there was an opening of about two inches in the cæcum.

After the various structures have disappeared, leaving little but the muscle and peritoneum, there may be marked symptoms from sclerosis of the nerves. The nerves of the appendix not destroyed become involved in the cicatricial contraction and frequently keep up a great deal of disturbance in this vicinity, and not infrequently the movements of the colon are inhibited. As a result we are apt to have chronic constipation. I have now removed several such stumps, and the patients have immediately felt relief.

The patient from whom this specimen was removed had had several attacks of appendicitis, and on removing the appendix I found that it was filled with nematoid worms. The cæcum is a favorite resort for the oxyuris, and I have no doubt that the presence of the oxyuris in the appendix not infrequently gives rise to an infection atrium.

Here is a specimen showing three distinct cavities with contractures between. It was extremely firmly adherent. This patient had a number of mild attacks, and once an abscess opened externally, and finally we were obliged to remove this stump containing three well-marked cavities similar to what we often see in pus tubes.

Among the latter forms is one represented by these two specimens. These were removed from a professor in one of our colleges. He was unable to stand and was compelled to give up his work for a year. On removing the appendix I found these two portions some distance apart. The little short stump represents the healed appendix. The lower portion was an inch and a half away from the stump. It was a focus of infection, and was kept alive by adhesion to surrounding tissues.

If we were to consider the complications of appendicitis this evening we should open up an enormous field. I shall simply show a specimen belonging to Dr. Willard. Here we have an abscess of the liver, which is not an infrequent complication, and probably occurs oftener than is generally supposed. In very mild cases, and in cases in which the infection has

been in progress for not more than two days, I have found infected thrombi in the mesappendix, which could easily lead to emboli and abscess of the liver. I am quite sure that this occurs in cases where appendicitis is not suspected. It is not necessary that there should be gangrene or extensive disease of the appendix to have mesenteric thrombosis and portal embolism.

SUBCORTICAL GLIOMA OF THE CEREBRUM AFFECTING PRINCIPALLY THE ARM CENTER; REMOVAL: RECURRENCE OF THE GROWTH; SECOND OPERATION; RECOVERY.*

ALFRED C. WOOD, M.D., PHILADELPHIA.

For the privilege of presenting the following report of what proved to be a rare and interesting case I am indebted to Dr. H. C. Wood, in whose service at the University Hospital the patient first came under observation, and Dr. J. William White, to whom he was referred by Dr. Wood for surgical intervention.

Briefly, the history is as follows: †

"W. B., aged twenty-eight years, of Irish descent, by occupation a bartender, states that he has always enjoyed good health until the beginning of the present trouble. Careful inquiry failed to elicit any family predisposition which would have a bearing on the present condition. According to his account he first noticed, in August, 1892, occasional twitchings in the left hand; these have recurred at irregular intervals up to the present time, until now they sometimes happen several times a day. They begin with a tearing sensation in the hand, movement and sensory disturbances, however, coming on almost simultaneously. The arm is commonly flexed at the elbow by tonic contractions, though the hand is clonically and furiously moved. Sometimes the attacks are not attended by loss of consciousness; usually, however, of late, the first movements are followed almost at once by unconsciousness and a fall to the ground, there being general muscular relaxation, except that the mouth is commonly drawn toward the left side. On two occasions there have been violent general epiliptiform convulsions. When he first came under observation there was no distinct paralysis of the arm, but a slowly progressive loss of power not yet amounting to complete paralysis has developed. There have been occasional attacks of vomiting. In the early history of the trouble he was free from headaches, but lately these have been more and more frequent and severe. The pain is located in the region of the right temple, and has been at times so acute as to preclude sleep for a whole week. There is also at present a rapidly progressive and severe double optic neuritis, with retinal hemorrhages and large tortuous retinal veins. Thirteen years ago, he says, he was struck on the top of the head with steel knuckles, possibly a little to the right of the middle line; the blow caused him to reel, and he was dazed for a few minutes, but did not lose consciousness. No further trouble was experienced from this accident. The reflexes are normal. The urine is free from albumin and sugar, the specific gravity is 1033, and the reaction is acid. There are no disturbances of the special senses other than the presence of diplopia and some contraction of the field of vision, which latter is evidently the result of the optic neuritis. The symptoms point to the presence of an organic disease affecting especially the motor arm centers in the cerebral cortex, and spreading upward to those of the face; possibly, also, affecting slowly the leg centers, as there seems to be some weakness of the left leg.

"I do not think it possible to make an absolutely positive diagnosis as to the nature of the organic disease, but I have no doubt from the way in which the case has progressed that there is some form of tumor present. The possibility of syphilis has been carefully considered and put to one side by a very active specific treatment which failed to produce any

*Read before the Philadelphia County Medical Society December 12, 1894.

†Abstracted from a clinical lecture delivered at the University Hospital upon the patient's case by Dr. H. C. Wood, in January, 1894.

improvement whatever. The important practical question is whether the tumor springs from the meninges or arises within the brain. Here again the diagnosis is simply one of probabilities, not certainties. It is to my thinking improbable that the tumor springs from the meninges. Early in the case pain was wanting, so that the headache from which he now suffers is almost certainly a pressure symptom and not the result of any localized meningitis or meningeal irritation. In the second place, the occurrence of an optic neuritis along with a cortical lesion, situated as high up in the vault as the present must be, would indicate great increase in the brain pressure. A tumor springing from the membranes and so located that in its first inception it would evince its presence by symptoms of irritation of the cortical centres, would, I opine, of necessity have produced, by pressure and secondary changes, complete destruction of the cortical centers by the time it had grown sufficiently to cause the violent pressure symptoms present in this patient. I believe, therefore, that the tumor is of intradural origin. It is probably not tubercular on account of the general good health of the patient, and it must therefore be in all probability sarcomatous or gliomatous. After a very careful consideration I have come to the conclusion to recommend surgical interference for the following reasons: The case is progressively going from bad to worse, and must soon end in death if surgery be of no avail; second, it is possible that I may be mistaken in supposing that the tumor arises from within the brain, and if a meningeal tumor should be found the result of surgical interference would of course be most brilliant; third, even if glioma or sarcoma of the brain substance exists, it seems to me possible to remove sufficient of the mass to relieve the intense pressure symptoms, and probably to increase the comfort and protract the life of the patient. I shall therefore send the case to Professor White for operation."

With such a history, in addition to the careful study already made of the case by Dr. Wood, it is needless to say that in the advisability of an operation Dr. White was fully in accord. The consent of the patient having been readily secured, the day previous to that set for the operation the entire scalp was shaved and well scrubbed with soap and warm water, then washed with alcohol and finally douched with a solution of bichloride of mercury 1:1,000 and carbolic acid 1:50, after which the head was covered with an antiseptic dressing wrung out of a solution of corrosive sublimate 1:2,000 and carbolic acid 1:100. The usual preparatory treatment for a patient about to undergo an operation of this magnitude was carefully carried out.

Operation, 1:30 P.M., January 24, 1894. After the administration of ether the cleansing of the scalp was repeated in the same manner as before. As the symptoms detailed above clearly pointed to implication of the arm center of the right cerebral hemisphere, the position of the fissure of Rolando on the right side was marked upon the scalp, having been determined by the method of Mr. John Chiene, of Edinburgh, which is as follows: A moderately heavy piece of paper at least five inches square is folded upon itself by bringing two diagonal corners into apposition, forming a triangle. This angle being one-half of a right angle is equal to 45 degrees. The free margin is then folded over so that it lies forming the angle whose value is one-half of 45 degrees, or 22.5 degrees. Now, by retaining the last fold and unfolding the first the sum of these two angles is obtained, which equals 67.5 degrees.

As pointed out by Thane, the fissure of Rolando starts on the line from the glabella to the inion, at a point 55.7 per cent. of the distance, measured from the former, and runs downward and forward at an angle of 67 degrees for a distance of about three and one-half inches, the lower extremity of the fissure running slightly more perpendicularly than indicated by the line. For practical purposes it is sufficient to measure half an inch behind the middle point between the glabella and inion at the upper extremity of the fissure. If now the angle of the folded paper, which represents 67.5 degrees be placed at this point with the straight edge along the middle line of the head anteriorly, the folded margin of the paper will represent the position of the desired fissure, which stops at three and one-half inches from the upper extremity. It is now well known that the convolutions at the upper end of this fissure control the movements of the opposite leg, while those at the lower extremity the muscles of the

opposite side of the face; between these the centers which govern the arm are located. Having fixed these points on the scalp with an aniline pencil, it remained to indicate their positions on the skull; this was done by means of a fine drill which was forced through the scalp and rotated two or three times to make an impression on the bone. A large horse-shoe-shaped flap with the base anteriorly, and consisting of all the layers of the scalp, was raised so as to expose the motor area, and the hemorrhage controlled by means of hæmostatic forceps. An inch-and-a-half trephine was applied over the arm center, as indicated by the mark on the skull, and the button of bone removed. The exposed dura was of deep purple color and tense and bulging, but was not adherent. The opening was then enlarged above and below with the rongeur forceps, to the extent of two and a half inches. Before the operation was begun it was decided to proceed after the method recommended for certain cases by Mr. Horsley, which consists in making an appropriate flap and removing the necessary portion of the bone. After the hemorrhage is arrested sterilized gauze is laid in the wound and an antiseptic dressing applied; the removal of the tumor being deferred until the patient has recovered from the shock of this procedure. After the dura was exposed, however, the amount of tension indicated so high a degree of intradural pressure that it was thought advisable to proceed further. The dura was very carefully divided and turned aside. The convolutions exposed were deeply congested and bulged into the wound, showing unmistakably that the seat of trouble had been exposed. Palpation did not throw any additional light on the condition, as there did not seem to be either distinct resistance or undue softening. An incision into the most prominent portion of the swelling revealed what at first seemed to be a cyst with a wide zone of altered brain substance surrounding it. The tissue around the cyst was dark in color, and contained a few small extravasations of blood, and upon closer examination was thought to be a new growth with secondary central softening, giving the appearance of a cyst. This mass was found to merge into healthy brain substance on its different aspects without any attempt whatever at encapsulation or of sharp demarcation. The removal of this tissue was effected by the cautious use of the knife, scissors and curette. It was impossible to remove it as a whole on account of its soft consistence, and it was therefore taken away piecemeal. There was no way of judging when the tumor had been entirely eradicated, but the operation was discontinued as soon as healthy brain tissue appeared to have been reached on all sides. The cavity left in the brain was about the size of a large walnut. Bleeding points were ligated where possible, a drainage-tube inserted, the wound packed with iodoform gauze to arrest the bleeding which still continued; the wound in the dura was closed by catgut sutures, except at the point where the tube and the gauze came out, the flap stitched in place with silkworm gut, and an antiseptic dressing applied. The operation was well borne, and the patient came up from the ether nicely, suffering only moderately from the shock. As the effect of the anæsthetic wore off it was discovered that the left side of the face was flattened and expressionless and when voluntary motion returned it was found that there was complete paralysis of the left arm and leg. At 10:30 P.M. of the same day motion began to return in the paralyzed leg, and by twelve o'clock, midnight, the patient was able to flex the limb and move it about. Sensation was not impaired. The course of the wound was satisfactory throughout, the iodoform gauze was removed on the second day, and the drainage-tube two days later; there was no discharge of pus at any time, and healing was prompt except at the point occupied by the tube, which closed by granulation. The paralyzed side of the face soon began to improve and went on to complete recovery. Motion in the arm began to reappear two weeks after the operation, but has made little improvement.

BOSTON MED. SURG. LIBRARY ASS'N MAR 30 1898

It was soon found that the scalp overlying the trephine opening in the skull was becoming elevated. This condition increased very rapidly until a tumor the size of an egg had formed in spite of continuous firm bandaging. The swelling was at first thought to be due to what is known as fungus cerebri, but it later became apparent that it was a recurrence of the neoplasm. There were no subjective symptoms of intracranial growth.

In May, having made the same preparations as before, a flap was dissected back from the swelling, the opening in the skull enlarged, and a considerable quantity of substance similar in character to that removed at the first operation was taken away. The distinction between the healthy brain substance and the tumor was more pronounced, so that the removal of all the growth could be made more complete and certain. There was very free hemorrhage, which, however, yielded to pressure, the wound was closed without drainage, and the usual dressings applied. The operation was immediately more serious than the first, but the patient again rallied well and was up and about again in a few days.

Since the moment of the first operation there has been absolutely no headache, no recurrence of the spasms, not even an abnormal sensation, and the vision, which was very imperfect before, now seems as good as it was previous to the beginning of the trouble.

Microscopic examination of the tissue removed showed the appearance of a glioma.

The patient left the hospital and passed from observation until about six weeks ago, when he stated that he had been entirely free from all symptoms during the interval. He walked well without a cane, although the left leg is somewhat spastic. The functions of the arm have not improved much. Since leaving the hospital, however, there has been no attempt to improve the condition of the limbs by massage or electricity, so that failure to make greater progress toward the restoration of the muscular tone of the left arm and leg may be due in part to this neglect. There is now some increase in the knee-jerk on the left side, indicating descending degeneration in the cord. The scalp over the seat of the former operation is depressed, as is always observed in these cases if the bone has not been replaced or substituted by a portion from another source. The part seems entirely healthy; there is no evidence of a return of the growth. The patient states that he eats well, sleeps well and is up to his usual health and weight.

The features of especial interest in this case are: (1) The accurate location of the growth clinically; (2) the precision with which the tumor was exposed by the trephine opening; (3) the immediate and complete left sided paralysis, followed by perfect restoration of the normal condition in the face and the return of a very fair degree of function in the leg, while motion in the arm has failed to improve markedly, showing that the arm center has probably been completely removed, while the face and leg centers were but slightly encroached upon at the operation, and although suffering temporarily from the traumatism, have preserved their integrity; (4) the recurrence of the growth followed by its successful removal, the patient remaining well until the present time, now seven months after the last operation and eleven months after the first; (5) the hemiparesis did not precede the spasms in this case, and myotonia was absent. It is claimed by Mills, Sequin, and others that both of these conditions are to be noted in the subcortical lesions of the brain, and in a case recently reported by Diller and Buchanan the convulsions were preceded by paresis.

The present position of cerebral surgery marks one of the great achievements of the healing art, and has been made possible entirely through the agency of modern aseptic technique. We do not now consider it a more serious matter to expose and explore the brain than the peritoneum. Unfortunately the affections of the brain are not so frequently suitable for surgical attack as are those of the peritoneal cavity. However, with the seat of numerous important functions of the brain already determined, with the constantly increasing certainty with which the neurologist is able to definitely locate the exact seat of numerous pathological processes, with the ability to cut down and expose these points with precision through a knowledge of cranio-cerebral topography, and with the present improved operative technique, the legitimate field of surgical interference must grow broader and broader. To-day it is not sufficient to rest with the diagnosis of a brain tumor; but, having determined its presence, it is incumbent upon the physician to extend to the patient the same opportunity for relief that would be granted him in other surgical affections.

It is evident that in order to successfully remove a tumor of the brain without taking the life of the patient it must be situated upon or near the convexity.

From a careful study of the post-mortem records of 600 cases of brain tumor by Starr ("Brain Surgery," 1893) there were found 46 in which an operation was indicated by the general and local symptoms, and in 37 (6 per cent. of the total number) the conditions were such that the tumor could have been easily removed. The average proportion of brain tumors that are favorably situated for removal, as given by various authorities from a study of post-mortem records, is 7 per cent. It is especially interesting to note that in the cases analyzed by Starr the tumor could have been removed easily and with safety to the patient in at least 78.7 per cent. of those in which the symptoms pointed to a growth in an accessible region. There is no doubt, however, that the number will be much greater in the future for the reasons already mentioned.

In regard to the mortality of these operations the same author, from a study of the operations so far reported, finds that in a series of 81 cerebral tumors the growth was successfully removed 54 times; of these 39 patients recovered and 15 died, the percentage of final recoveries being therefore 48.14.

Erb reports a case (quoted by Starr) which is so similar to the one just detailed in many particulars that it is here reproduced.

The patient was a man who had suffered from the general symptoms of brain tumor, viz., headache, vomiting, vertigo and optic neuritis for some months. The development of occasional spasms, followed by paralysis in the left arm and leg, indicated the central convolutions of the right hemisphere as the probable position of the tumor. Czerny operated in November, 1890, and found the tumor to be an infiltrated glio-sarcoma, and removed a part of it, its complete extirpation being impossible. The patient recovered from the operation, was very much improved for eight months, and then began to suffer from the old symptoms. In November, 1891, his condition had become so bad that it was thought best to repeat the operation. The tumor was found to have grown again, and a large part of it was removed. Again improvement was very striking, but at the date of the report—July, 1892—a third operation upon this man was in contemplation, the symptoms having reappeared.

As a result of his studies, Starr states that the large majority of the gliomata and the glio-sarcomata were infiltrated in the brain substance to such an extent as either to have escaped detection at an operation or to have been impossible of excision. When it is considered that this statement is based upon a study of 600 cases, the one here reported must be considered as having terminated unusually successfully.

The cause of these tumors is as obscure as is that of those situated upon other parts of the body. In a large number of the cases a history of traumatism will be obtained, but whether or not this has any etiological bearing it is impossible to say. The patient whose case is detailed above reports having received a blow on the head thirteen years ago. At the time of operation there was no evidence of injury either to the scalp or in the skull.

CLIMATOLOGY IN CIRRHOTIC RHINITIS.*

C. ROBERTS BINDER, M.D.,† PHILADELPHIA.

The pathological changes in atrophic rhinitis present a subject for much controversy—pathologists differing in their *à priori* investigations. Therefore a clinical *à posteriori* reasoning is accomplished under difficulties which induce factionalism as to whether the tissue metamorphosis is the result of a progressive hypertrophy, or has it its own isolated causes classing it as an affection *per se?* Nevertheless, we have a cirrhotic state to combat. Let it be the result of a hypertrophy, as claimed by some researchers, or the result of a pathogenic coccus or bacillus, as accounted for by others, it still maintains the same course that scleroses do in other organs. That is, a prolific development of tissue cells, in various

*Read before the Philadelphia County Medical Society, December 12, 1894.

†Chief Assistant in the Department of Laryngology and Rhinology to the Medico-Chirurgical Hospital.

stages from round cells to developed cicatrices, causing the caseous degeneration of epithelium, which result is directly due to a progressive contraction. This contraction, while homologous to the scleroses in other organs, owing to the situation, is more accessible and, consequently, more amenable to treatment by atmospheric changes, and directly subject to increased exacerbations when the surroundings are unfavorable. As for myself, I feel complacent over the fact that climate reveals to me measures of pronounced success in the amelioration and possible cure of this odious disease. As for local applications, my experience has been futile, though at the same time I have persevered. Likewise, I do not doubt that this is the experience of all practitioners in the treatment of this stubborn malady; and hence it behooves the thoughtful rhinologist to consider some method at his disposal which will enable him to locate the patient upon a vantage-ground, where the morbific changes will be inhibited and the remnants of healthy tissue and glands be stimulated to normal physiological action, overcoming gradually a lesion that ridiculed a therapeutic medicinal treatment.

The paramount evil is apparent in this affection as in all chronic diseases—social ostracism. Truthfully, it is more apparent here than in some others; the offensive smell which is noticeable in the large majority of cases not only renders them unfit for many offices of social man; but it must be constantly a reminder of their infirmity, inducing melancholia and other psychical phenomena. The results of this condition can be depicted by observing physicians: that deplorable state which they have seen among the hopeless—the epileptics, the maimed, the phthisical and the insane. Since colonization has done more as a restorative to the epileptics than have medicinal or operative measures, and the healthy offspring of the tuberculous immigrant in Colorado demonstrates what can be done for the afflicted who fear nature's law of heredity, the scientific climatologist conjectures wisely when he considers "what might be done for the chronic invalid in colonies, established in suitable places and arranged politically, that they might compete with their fellows for a livelihood." This would not only be a step toward Utopia, but a lesson of philanthropy that only could be accomplished by the highest grade of civilization, urged and abetted by a compassionate humanity. Moreover, when morphology—and this refers more especially to morphological teratology and embryology—is established systematically in medical diagnosis, then will the treatment of many chronic diseases resolve itself into colonization. The reason of this is patent, for the profession will recognize more explicitly causes of evolution and also those of atavism.

Ozæna, the prevailing symptom, though sometimes absent—as I have seen it—is by no means diagnostic of the condition. Ozæna may be the result of tuberculous, syphilitic and carious ulcerations, and even a result of accessory disease, although Drake claimed originally that atrophic rhinitis never existed unless accompanied by antral, ethmoidal or sphenoidal disease. Since, according to my view, the ozæna is due to the caseous degeneration of epithelium, this symptom is dependent entirely upon the intensity of the cirrhosis and, if I may be allowed to introduce E. Frankel and Krause's theory, the diathesis and environments which favor the propagation of the "bacillus fœtidus." Why the *bacillus fœtidus* evinces itself in some cases and not in others is a question that should be settled by the department of bacteriology, although the clinician is fully aware that the diathesis, surroundings and other incidentals dependent upon the vocation of each patient augment the development of this bacillus. Moreover, the site of the lesion is in itself a septic location, which is modified by the anatomic conformation of each individual's nose which is unfortunately attacked. This truth is another clew which the morphologist can employ in the revelation of the mysteries of anomalies and reversions. I have seen the typical nose of the anatomist's chart in clinics, but I have never seen two identical nasal chambers, either in a physiological or pathological state. Therefore the normal structure, prior to the pathological development, is the foundation upon which the intensity of the lesion depends; hence the peculiarity of each individual case.

The lesion involves the nasal portion of the respiratory tract, and, in my estimation, any lesion implicating this tract, whether in the peripheral or central por-

tion, prevents proper aëration of the blood. Hence the anæmia varies proportionately to the amount of tissue involved in this cirrhotic process. Notwithstanding, the anæmia should be treated with hæmatinics and bracing atmosphere in which there is an abundance of oxygen; the mountains of Pennsylvania and New York in summer and the Atlantic seaboard in early spring fulfill these requisitions. Secondly, the patient's temperament should be considered. I should divide disposition into two states: irritability and repose. The general rule is, usually, infrangible, *i.e.*, light-complexioned mankind belongs to the reposed in temperament, while dark-complexioned are irritable. In the selection of an abode of health for the afflicted, the above must be well borne in mind; as it is of the utmost importance to send the irritably inclined to climates which are of a sedative nature. Contrarily, the reposed should be sent to stimulating resorts, where animation will cause them, in part, to forget their malady.

The primary requisite in promoting the domination of the healthy titsue and fostering a metamorphosis in the disorganized structure in all cases is outdoor life; that is, not a definite length of time each day, but if it is possible to remain in the atmosphere twenty-four hours it will the better accomplish the desired result. The sleeping apartment should be roomy, and a free circulation of air should be active during the sleeping hours as well as when the room is unoccupied. Above all avoidances steam radiation should be placed. The dry air should be eschewed at all times, for the reason that the sufferer with cirrhotic rhinitis—unless the pathological surface is of small area, and this I have never seen—cannot infuse the inspired air with sufficient moisture to insure a salutary influence upon his economy. Extreme cold should be shunned, and also localities that are extolled for dryness, per example, Colorado and New Mexico, in the United States, and Egypt abroad. One of the worst evils which characterize these places is the violent sand-storms within their domain, causing a mechanical irritation to a membrane passing through the various stages of chronic inflammation, and also causing a painful nasopharyngitis. In all cases that have come under my notice in Philadelphia, subjectively and objectively, the disease has been augmented during prolonged dry and cold spells. Contrarily, the summer months, especially the moist, warm days, benefited and relieved the patients and checked the process of destruction.

The abode and climate of preference, from which superior results will be obtained, is one, the composition of which consists of: picturesqueness, warmth, balminess, equability, stimulation or sedativeness (according to the temperament of the patient). Of these conditions I shall speak separately.

Picturesqueness affords solace to the restless and fosters a feeling of joy and careless demeanor in those who are morose. In fact, there is nothing so free of sickly contamination as an ever-varying landscape.

Warmth is the next quality which I wish to extol; and by warmth I mean a temperature of over 70° F., and it may range to 84° F. This is requisite for two reasons; it aids in moistening the inhaled air, and, owing to its mildness, the small space of healthy tissue can perform its function admirably. Cold air, on the other hand, not only cannot impregnate itself with moisture, but it is deleterious to the healthy membrane and causes its hasty destruction. The second reason for warm air is the opportunity that it affords for outdoor exercise, without bundling in swaddling-clothes, which impede free circulation and interfere with the glandular system. This system must be kept as near perfect as possible if a cure is to be hoped for in rhinitis cirrhotica. Moreover, accompanying this affection, or rather as one of the sequelæ, is a functional disturbance of the aural organ, due to agglutination of the mouths of the Eustachian tubes in the naso-pharynx. The dripping of viscid mucus from the nose is responsible for this plastering process. Warmth, combined with a moderate relative humidity, is not only a preventive of this troublesome symptom, but a positive relief in cases of some length of duration.

Balminess is a combination of moisture and sunshine tempered with warm currents such as would be blown from the ocean by light breezes, and experienced in resorts along the southern coast of California, eastern shores of Italy, and that delectable country of southeastern France and adjacent Italy washed by the shores of the Mediterranean Sea. It insures the fatuitous victim from the fear of "catching cold,"

and for this reason allows him to take outdoor exercise with a feeling of immunity. The moisture in a balmy atmosphere is due to the degree of relative humidity; the latter is directly dependent upon the influence that the absolute humidity has upon the temperature. Since warmth is a component part of the climate I have recommended, it is well to observe that an extremely damp locality be avoided, for the results which are hoped to be obtained from moisture will not be forthcoming, but instead the patient will suffer from a high degree of relative humidity. In order to avoid excessive humidity, it is well, according to meteorological observations, to eschew extreme temperatures.

The equability of which I have spoken as a factor in the selection of a suitable domicile for atrophic conditions of the nares applies more to the equability of the *warmth* which I have already described. Coasts or islands washed by warm ocean currents are to be mentioned as possessors of equability. Truly all large bodies of water avert the rapid rise and fall of the temperature wave. It is needless for me to explain his phenomenon, but I should like to make an exception, and that is the great lakes of America, the confines of which are visited by most severe rises and falls of temperature in a short period of time. The direct cause of this, I think, is the plateau-like situation of these lakes, as this is not true of Salt Lake, which is a basinic region, though elevated at the same time some 4,000 feet.

In the "Transactions of the American Climatological Association" for the year 1890, Dr. A. C. Standart gives a statistical study of the climate of this region; and as a winter resort, for equability and bracing tone, a better selection would be difficult to make in cases of rhinitis cirrhotica. It is not cold enough to hinder outdoor exercise. Moreover, this degree of cold would act as a massage to the healthy tissue of a patient whose atrophy was of a low grade; but for bilateral cases with small area of healthy tissue in the nares, I prefer the southern oceanic treatment, either upon a suitable island or a sea voyage.

It is with some regret that I speak of sea voyages, knowing that there is not the desired facility. There are no planned voyages by steamers departing from any of our seaports for southern sea benefits, calling at stations of interest and salubrity, so that the only expedient is a sojourn upon one of the islands in the Atlantic Ocean, such as the Bermudas, Azores or Madeira Islands, combining equability and sedativeness.

The last qualities that are necessary considerations in the choice of selection are influences which bear upon the corporeal and mental faculties of the individual; they are sedativeness and stimulation. I have previously classed the variety of patients which improve best in climates possessed of one or other of these attributes. Sedativeness will be found in localities or resorts whose air is balmy, mild and bright, and whose elevation must not exceed 400 feet above the sea-level. As stated before, the following islands are unwavering examples of this character: The Bermudas, Azores or Madeira. Stimulation is found at high altitudes, ranging from 500 feet to a mile above sea-level. Of the resorts which combine equability and stimulation, I may mention Nice, Mentone, Cannes and Villefranche on the shores of the Mediterranean; but, by preference, according to many climatologists, the islands in this sea are superior—Capri, Malta, Majorca and Sardinia. In the Atlantic Ocean the Canary Islands are noted for their stimulating attribute, and in the Pacific mention may be made of Western Australia. The southern coast of California has an atmosphere the volume of which is equable and stimulating. The counties of that State bordering on the ocean are Santa Barbara, Ventura, Los Angeles and San Diego. All of these resorts have improved hostelries, and home comforts can be partaken of very liberally. Therefore the physician need not hesitate to give his patients contrary advice owing to lack of accommodations.

In conclusion, I wish to state that recently two cases of atrophic rhinitis of which I am familiar developed tuberculosis of the lungs. Therefore it appears to me that there must be fibroid changes in other organs, following the progress of the disease in the nose; or, while the destruction is active in the nasal organs, it is a suitable and favorable opportunity for the ingress of the tubercle bacillus. If this presumption cannot be refuted, then we have additional reason to treat this affection upon a climatic basis, both to prevent *this* result and to hasten the subsidence of the nasal lesion.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JANUARY 12, 1895.

EDITORIAL.

A FICTION OF FIGURES.

That "figures cannot lie" may be true, but the disability does not necessarily extend to the intelligence manipulating them. "Let us do the counting," said a partisan electoral board, "and we don't care who votes or how!"

However true statistic figures in the abstract may be, when regarded as members of an equation they are factors whose values depend entirely upon the positions they occupy in the equation. By selecting some and suppressing others of a group of correlated statistic items, a result the converse of truth may be given the appearance of mathematical demonstration. So common is this process that the paradoxical belief is that the "figures which will not lie" are the most notorious of prevaricators.

An example of the evolution of a falsehood by a process of artificial selection and carefully devised environment is found in the following clipping which has of late been going the rounds of scientific periodicals. It is one of those clips that pass as the right to work mischief by furthering wrong:

"The British Medical Association, wishing an exact statement of the influence of alcohol over the duration of life, charged a commission with the inquiry in three classes of subjects:

"1. Total abstainers.

"2. Moderate drinkers.

"3. Excessive drinkers.

"Observations included 4,234 cases of death in five categories of individuals; below is the average attained by each class:

"1. Abstainers—fifty-one years and one month.

"2. Moderate drinkers—sixty-three years and one-half month.

"3. Occasional drinkers—fifty-nine years and two months.

"4. Habitual drinkers—fifty-seven years and two months.

"5. Drunkards—fifty-three years and one-half month.

"The most advanced age is attained by moderate drinkers and the minimum by abstainers."

There is no reason to doubt the accuracy of these figures as separate items. The falsehood is in the segregation of these items, suppressing all correlative facts and declaring the result as the final solution of the general problem. It would be stultifying to entertain the possible accuracy of conclusions which subvert all facts accumulated from observation, experience and experiment, which contravene the data on which are founded the unsentimental business principles of life-insurance corporations, and which willfully misrepresent the scientific body under whose authority they claim authenticity.

The *British Medical Journal* gives the following explanation of these figures:

"The attempt to construe the statistics published by the Collective Investigating Committee of the British Medical Association as proving that intemperate drinkers live longer than teetotalers is quite unwarranted, and is in direct opposition to the conclusions of the reporters themselves as expressed in their report. Teetotalism, as they suggest, has only of late years been largely practiced in Britain, but drinking to excess has had great antiquity; therefore the average age of living abstainers must be less than the average age of the rest of the community. So that the average age at death of abstainers being 53 years as against 58 in the case of drunkards at death proves nothing against abstinence. The accuracy of this explanation is proved by other tables given in the report. When deaths under 30 years were excluded, the average age of the abstainers was about four years more than that of the decidedly intemperate. When deaths under 40 were excluded the average age of the teetotaler at death was more than five years greater than that of the intemperate. To guard against misrepresentation or misunderstanding, the committee expressly stated that the returns reported on afford *no means* of coming to any conclusion as to the relative duration of life of abstainers and 'habitually temperate drinkers;' that habitual indulgence in alcoholic liquors beyond the most moderate amounts has a distinct tendency to shorten life, the average shortening being roughly proportionate to the degree of indulgence; and that total abstinence and habitual temperance augment considerably the chance of death from old age and natural decay."

Shall We Quarrel With Our Neighbors?

It is unnecessary for us to adversely criticise our medical neighbors. Assured of our principles we need not contend with those who decry us, but can pursue our way without fear of successful antagonism. Honest differences of opinion should be discussed frankly and without passion. Inuendo and abuse are not argument. Life is short at most; days come and go and we pass away. Let us, then, not spend time in recrimination. He will succeed best who quietly pursues his calling, not finding too much fault with his neighbor; rather endeavoring to show his superiority by works than words. Your friends will fight your battles for you. Success in the treatment of your patients is the best ammunition you can furnish your adherents.—*Ec. Med. Jour.*

Blood-Serum in Surgery.

Dr. Schleich, of Berlin, regards desiccated pulverized and sterilized blood-serum as the best dusting powder for wounds and as the most unirritating vehicle for medicaments of all kinds. When applied to fresh wounds it forms a crust under which healing takes place, while in cases of moist eczema, burns, etc., it arrests the secretion. It may be mixed with water to form a paste, which is also an excellent vehicle for various drugs.—*Allg. Med. Central. Ztg.*

ABSTRACTS.

THE EFFECTS OF ALCOHOL ON THE ENGLISH MILITARY AND CIVIL POPULATION AT HOME AND ABROAD.

In an inaugural address before the Ulster Medical Society, November 2, 1894, Brigade-Surgeon F. E. M'Farland, A.M.D., said (Dublin *Jour. Med. Science*): There is one subject which bears more than any other on the health and well-being of the nation, and that is the drink question.

During twelve years' residence in India I had an opportunity of seeing its effects in that country. India is a remarkable country in many ways, and our tenure of it is one of the greatest miracles in history. How England, with a handful of men, many of them invalids, has been able to keep a population of much over 200,000,000, not in check but in absolute submission is the marvel. Now there are different ways of accounting for this. The population of India consists of Mussulmans and Hindoos, and if the English were out of India to-morrow these would be at war with each other, and the Mussulman would most likely prevail. Another reason is that though both races hate us as an alien race in their country they respect our laws; but another and perhaps the greatest reason that we hold India is—the two races, Mussulmans and Hindoos, are a sober people. Mahomet taught his people not to drink, as it made men mad; and Brahma and Buddha taught their followers not to touch strong drink, as it is an unclean thing. The result is, I may say, there is hardly any drunkenness among the natives of India, and an English lady might land at Bombay or Calcutta and travel to almost any part of India, and she would never meet with an insult or incivility, and that, not because they have a respect for women, for the reverse is the case, but because they are a sober people, and know that the matter would be reported and the offender would be detected and punished.

Some time since it was proposed to establish an "out still" system in India, which simply means public-houses under government license, with the object of raising revenue. My belief is that if this were done, and that drinking habits could be introduced among the natives, we could not hold the country a single year; it would become a perfect pandemonium.

I entered the army in the year 1858, and was at once sent to India, at the close of the Indian mutiny. At the close of a campaign discipline is apt to be a little relaxed; and certainly, in numerous cases, both officers and men had contracted drinking habits to a considerable extent. I have seen some of the most promising fellows in the service go shipwreck from strong drink. I was on the staff for one year, doing duty with various corps. The next year, 1859, I was gazetted to my first regiment. It was a distinguished regiment—had been to the Crimea and lost half of its men at Inkerman; but, like most other regiments at the time, it was a fine old drinking regiment too. There was no temperance society in it, and the colonel, who was the soul of honor, would not allow one, feeling that a man would be more demoralized by breaking his pledge than by drinking. In India, except in large cities like Calcutta or Bombay, there are no public-houses—the regimental canteen serves the purpose; but there are spirit merchants in every station.

There was a good deal of sickness in the regiment during a great part of the time I was with it, and many fatal cases, attributable to drink, especially among the non-commissioned officers. At this time there were two issues of rum in the day. Each issue, or tot, as it was called, was about 2½ ounces. In the days gone by there were four issues, the first at early dawn; and even the drum-boys were compelled to take their tot the same as the men. I returned to England in 1866, and during the eight years I remained at home my experience was that when men were in a large town or city like Woolwich or Belfast they drank, deserted and filled the hospital; but when they went into camp they were sober, well-conducted and healthy. In Aldershot—which is called a camp—there are enough

public-houses in all conscience. Every second house in the district is a beer-shop; but as there are no rich civilians foolish enough or weak enough to treat them, it is a case, as a soldier jauntily expressed it, "We calls for drink after drink, and seegar after seegar, as long as the blooming sixpence lasts." The government is wise in the payment of soldiers; they are paid in kind and not in cash, which would only be spent in drink.

In the year 1874 I returned to India, after an absence of eight years. A change had come over the spirit of the scene, and principally through the efforts of one man, the Rev. J. Gelson Gregson, the Father Mathew of India, I think the most remarkable man I ever met. To say that he traveled through every station in India is nothing—he did it two or three times a year. In the hot season, when it blew like a furnace; in the rainy season or the cold—all was the same to him: he went from station to station strengthening the temperance societies which he had organized in every regiment. Some commanding officers were favorable to those societies, some were not, more just tolerated them, but it mattered not to Gelson Gregson: he went on with his good work, and certainly I found a wonderful change since the time I was in India before. Not only were there a great number of teetotalers among the men, but there was a temperance element introduced into the service that never existed before, and this had spread to the whole Eurasian population, transforming them and improving them in every way. Mr. Gregson also introduced a form of pledge which, while it does not bind for a single day, is the one that is found to bind for life. It only binds a man while he keeps it in his possession. He can tear it up whenever he likes and be free from his obligation.

Also at this time, instead of two issues of rum only one was allowed, and in the last regiment I did duty with even this issue was divided into two. The canteen opened at a quarter to seven in the evening for the first half and at a quarter past seven for the second half. The canteen was again opened at eight o'clock, when a man could buy, at his own expense, a glass of spirits or a bottle of beer; but even this was productive of bad effects. Owing to the intense heat in the hot weather (and the hot season is very long) the men suffer from various affections and fevers, and from neurasthenia or nervous exhaustion generally. The result is that thirst is trying, and when in addition they take spirits at the canteen, the desire for more becomes almost imperative, and in too many cases it leads to men taking native drink. Many and curious are the ways the men adopt to obtain this poison, which is very deadly in its effects. I will not take up your time by describing the different kinds; all vary in strength according to the length of time they are allowed to ferment, and are a great cause of hepatic abscess and other illnesses. We hear a good deal in India of sunstroke, sometimes called heat apoplexy, insolatio or ardent fever, and that it is more common at night when men are in their beds than when out in the sun. My experience and that of others was that in too many cases the men had taken spirits largely before going to bed, and that, although they died of sunstroke, drink was the cause.

What is the state of things now in India? Lord Roberts crowned his splendid tour as commander-in-chief of India by wisely abolishing the rum ration entirely. We have now an army in India of about 75,000 men; of these 25,000, or one-third, are teetotalers, and a temperance element is developed through the whole army in India greater than ever before known.

Lord Wolseley says in a letter to the grand secretary Independent Order of Good Templars: "There are yet some great enemies to be encountered, some great battles to be fought by the United Kingdom, but at present the most pressing enemy is drink. It kills more than all our newest weapons of warfare, and not only detroys the body but the mind and soul also. All movements intended to meet this foe commend themselves to me, and no one can wish the Good Templars success more than I do. I am glad to say we have now but little drunkenness in the army—less of it in our ranks than in any other class of her majesty's subjects. To this fact I consider we owe much of the improvement in every respect that has been steadily going on among us for the last twenty years." These are the words of England's greatest general.

We tried large quantities of stimulants with our soldiers when we first acquired

India, and found the result was sickness, mortality and crime. Then we tried a smaller quantity with improvement, then smaller still with increased benefit, then no spirit ration at all, with the best results. We have the finest army we have ever had in India—sober, well conducted and healthy as an army can be in the climate which varies so much. One station may be healthy and the station next to it the reverse. I know temperance does not deserve all the credit for the improved condition of things. Sanitation, improved cooking, extra accommodation in hill stations—we have barracks for 14,000 now in the hills—but no one can deny that it is to the improvement in drinking habits principally that the great change is due.

Is alcohol food? If it be, it is a food we seem to get on very well without. This crucial question I am not going to solve; but, in the fewest words, put the matter before you. I may say there are two parties. One party believes that alcohol is neither assimilated nor changed, but is expelled as something foreign, by the kidneys, lungs and skin principally. The other party believes it undergoes combustion in the system, producing heat and force, but what the combination is they cannot tell us.

There are many kinds of alcohol, notably six—methylic, ethylic, propylic, butylic, amylic, capriolic—but it is with ethylic we have to do, C_2H_6O. The theory of Baron von Liebig was long believed, that the whole of the alcohol was consumed in the body; but French chemists—Lallemand, Perrin and Duray—performed a series of experiments in 1860 proving that alcohol was eliminated from the system unchanged. These experiments were performed by distillation and condensation, and by causing persons who had taken alcohol to breathe through a tube into a vessel containing bichromate of potassium and sulphuric acid in solution, and in such cases the color of the solution was changed from red to green, though no change took place when persons breathed through who had not taken alcohol. This seemed to settle the point, when the late Dr. Anstie performed a series of experiments, and he found that only a small portion of the alcohol was so eliminated and maintained that the remainder was consumed in the body, in a sense forming food. The late Professor Parkes, in his reply to him, said that, if a food, Dr. Anstie could not say whether it were a food for good or for evil. Richardson, in his Cantor lectures, admits that the whole of the alcohol drank is not recoverable, and suggests that probably it may have been converted into aldehyde, which by a process of oxidation is again disposed of within the body. I think we can leave this interesting question in the hands of the chemist, and with the proofs we can learn from our Indian army, and from the hundreds of thousands of our civil population at home who do not touch alcohol, we can say that if alcohol is food it is food for evil, and a food that we are better without. There are many excellent definitions of food given by eminent physicians and scientists; but plainly it comes to this, that food is that which produces bodily heat and forms tissue, and so force. That alcohol produces animal heat is disproved by Richardson, by a series of experiments on men, animals and birds. He shows that there are four stages in drunkenness. In the first, which is pleasurable, the heart is stimulated and quickened, the capillaries are dilated, there is a rush of blood toward the peripheries, with a very slight increase of heat, half to one degree; but he shows that this is really a cooling process, for the blood gets cooled at the surface of the body; and, in the second stage, sinks below normal; and, in the third stage as it approaches the fourth stage, the temperature becomes so low as to become dangerous, three or four degrees below normal. How alcohol forms tissue, except by causing fatty depositions, it is difficult to understand, as it does not contain nitrogen.

That alcohol is not a producer of heat is proved by experience. All arctic explorers give their evidence against it. All the men who took alcohol suffered more than those who did not—so much so, in most if not in every arctic expedition its use had to be discontinued.

The effects of alcohol on our civil population at home we find appalling. We spend about £140,000,000 on strong drink. To estimate the magnitude of this sum, we learn that it is more than the rental of all the houses and of all the farms in the United Kingdom. The rental of all the houses in the United Kingdom of England, Ireland and Scotland

is only £70,000,000, and of all the farms £60,000,000, making £130,000,000, and we drink £140,000,000. This is a fearful waste; but it does not end here. It is calculated that the country loses some £50,000,000 through the loss of labor—men not working their full time. Then there is some £30,000,000 expended in prosecutions for crime, legal expenses, prisons, poor-houses, lunatic asylums, and a hundred and one other results of intemperance. Another heavy loss which cannot be computed arises from the early deaths and sickness of workingmen in their prime. It may be said that we doctors have nothing to do with those matters; but we have everything to do with every matter which bears on the public health, and have as much to do with the prevention as with the cure of disease. Dr. Norman Kerr puts down 40,000 as the number who die annually in this country from strong drink *directly*, and about 60,000 who die *indirectly;* and these figures have been confirmed by the committee appointed by the British Medical Association and also by that appointed by the Harveian Society. Others consider these figures much too low and would certainly double them. And we ourselves know how many cases there are returned as pneumonia, liver, kidney, lung and heart diseases who have just drank themselves to death; but, in respect for the feelings of survivors, no mention is made about the drink, but the actual cause of death is sent to the Registrar-General.

The case of the drunkard is hopeless so long as he drinks. For him there is only one remedy, and that is, "Do not drink." He must not touch alcohol in any form if he wishes to save himself. But, unfortunately, the family of the drunkard suffers. Children require pure air, wholesome food and sufficient suitable clothing, and should have proper education. The children of the drinking artisan or workingman at night are often crowded in close, ill-ventilated rooms, breathing and rebreathing the same foul air—no more fruitful source for developing phthisis and struma; often little or no bedclothes, but huddled together for warmth. They are tea-fed and underfed. We can see them on the severest days barefooted and underclad, and we can tell the children of drinking parents from those of sober. Education is all very well if children are sent to school after a good breakfast and comfortably clad. And it is better that they should be barefooted than that they should be ill-shod and sit in wet shoes. But the drinking fathers and mothers care little so long as they can gratify their horrible craving for drink. People talk of the children of the poor being hardy. It is not so in towns and cities. The mortality is out of all proportion greater than that of the well-to-do classes. The only remedy is to remove or properly control the plague-spots of temptation—the public-houses. This can only be done by the mighty *vox populi*, quietly and lawfully and at the polls. Too long have the artisan and workingman paid their tribute at the expense of health, happiness, and everything that makes life worth living for, to enrich the publican and enable brewers and distillers to amass colossal fortunes.

Dr. Ringrose Atkins, a distinguished psychologist, microscopist and photographer, gave a most interesting lecture on the disastrous effects of alcohol on the vessels and nervous matter of the brain, exhibiting photos of sections of brains of alcoholics. I am not a profound pathologist, so will just quote Dr. Atkins' words. He considers in the early stages of alcoholism the most important and constant changes are "excessive nucleation of the vessels (arterioles), with consequent involvement of their coats and diminution in caliber of their lumina, and increase in the number of the neuroglia cells, both protoplasmic and fibrous, as Bevin Lewis and Andrietzen have pointed out. The nerve elements, both large and small cells, are affected in the later stages, undergoing either pigmentary or fatty degeneration, or shrinking and breaking up into molecular masses, with infiltration of nuclei." Dr. Atkins does not hold that these changes are special to alcoholism, or only found after its abuse. Nearly similar changes are found in other diseases and conditions of irritation, and the later changes are found in cases of chronic dementia, old standing paralysis, etc. Dr. B. W. Richardson, in his course of Cantor lectures, shows the action of alcohol on the blood if taken in sufficient quantity, by either fixing the water with the fibrin or extracting the fibrin, and so producing coagulation; on the red corpus-

cles by extracting water from them owing to the powerful affinity alcohol has for water, and in doing so altering their shape and course; also its effect on the vessels themselves. He shows especially how alcohol acts on the colloidal membranes—that the skin which covers us is colloidal, all organs and blood-vessels to their minutest ramifications, all organs, nerves, muscles and their fasciculi are sheathed with colloidal membrane, as well as the whole of the alimentary canal. It covers and penetrates the liver, kidneys and other solid organs. It not only supports the tissues and keeps the body in position, but it acts as a filter, and its efficiency depends upon a proper supply of water. He shows how alcohol acts on this membrane by robbing it of water and so producing thickening, shrinking and inactivity. In order that these membranes should work rapidly and equally they require at all times to be charged with water to saturation.

The effect of alcohol on the liver is first to cause congestion and then to shrink and contract the capsular membranous portion, so as to compress the vascular and cellular and so produce the hobnail liver in due time.

In the first stage of drunkenness an inordinate amount of arterial blood is sent to the brain; there is also dilatation of the capillaries; then comes the subsequent changes—there is venous congestion, and so in all the stages there is compression of nervous substance from disordered circulation.

From the effects of alcohol on the organs and tissues we can understand the different diseases it produces and develops. I need not speak of these.

The case, then, is that drunkenness is both a disease and a vice, and the question is, Where do these begin? One party says that moderate drinking is no vice; it only becomes a vice when a person exceeds. The other party says that moderate drinking is the vice that leads to excess, which becomes disease.

I am not going to touch on the drunkard's bodily ailments and diseases, but state that alcoholism is a disease characterized by many and peculiar psychological symptoms, of which loss of will-power, more or less complete, is one. It is computed there are 60,000 drunkards in the United Kingdom, and as many more qualifying for the position, and every one of these was recruited from the army of moderate drinkers, which is an item against moderate drinkers. No drunkard became so intentionally, but through loss of will-power and inability to resist the temptation. This inability may be hereditary or acquired. We have all seen instances of this. Alcoholism is both an insanity and a cause of insanity. Authorities vary very much as to the percentage of admissions into lunatic asylums from drink. The late Lord Shaftesbury, who was for fifty years on the Commission of Lunacy and for fourteen years its chairman, testified before a parliamentary commission that 50 per cent. was due to drink, and afterward stated that sixth-tenths were due to no other cause; the Thirty-ninth Report of the Commission in Lunacy put down 13.2, and many institutions vary. All authorities admit that a large number of admissions are from drink directly, but there is a worse phase—that a large number of lunatics are children of drunken parents. Some authorities put down one-half of the idiot class as such. There is a new school now that denies this, and says that acquired character cannot be transmitted to posterity. I cannot enter into this. At any rate, total abstinence is the safest and the only safe course. The inconvenience is very transient and the satisfaction very lasting.

It is by no means individuals of a low, vicious or brutal type, or the idle or those of a dull, inferior temperament who are usually the victims of strong drink. Often it is the young, the beautiful and the brave; the generous, the talented and the good. We should, therefore, treat habitual drunkards quite differently to the way we do. The habitual drunkard should not be let at large; he should be put into confinement, where he could pursue his trade or calling, or earn money in some way. A Norwegian gentleman in this city told me they used to have a law in his province of Norway that when a man was an habitual drunkard, any burgess could get another burgess to investigate the case—these burgesses were citizens sworn to maintain law and order and were men of character and of certain property-worth. These two witnesses, if they found that the man was an habitual drunkard and systematically neglected his family, could report him to an official

who was a kind of judge, and he then appointed two other citizens, independent of the two former and of each other, and on the evidence of the four the accused was without further trial put into prison for one year, and his family provided for by the State. The law worked well. I do not know if it is the same now; my friend has written to a lawyer in Norway to find out for me.

Alcohol is characterized by another symptom. Sometimes there is no depth of degradation to which the drunkard will not descend. I know of the case of a man of English blood who sold his two little girls to a Mussulman in a bazaar in India for a case of half a dozen bottles of brandy. But cases just as bad occur at home. You all know plenty of them. I need not dwell on the subject; it is part of the disease. There is a consensus of authorities who put down nine-tenths of all the crime in this country to alcohol. The late Baron Dowse, one of our Irish judges, said that drink was at the bottom of nearly every case he had to try, and that even in cases where it did not appear on the surface, yet, on investigation, he could nearly always trace them to drink. In the army, owing to the splendid discipline, practically there is no crime apart from drink.

But it is not at home only that we see the terrible effects of drink. We have, as Canon Farrar says, girdled the earth with a zone of drink. We send our sons to the colonies, and for one who succeeds how many go shipwreck because the spirit-seller is there before him. Our missionaries bring the Gospel to foreign lands, but in the same ship will be the spirit-seller or his wares to undo the work of the missionaries. Our missionaries complain that while the Mahometans make converts in great numbers, both in Asia and Africa, the heathen will not become Christians owing to their drinking customs. Mr. E. R. Barrett states that from 1883 to 1887 30,000,000 gallons of spirits were imported into Africa, and that an analysis of some of it proved it to be of a very poisonous quality; but what can one expect when a pint bottle sells at Sierra Leone at fourpence halfpenny? I do not mean to say that England is to blame for all this. I dare say other nations send spirits there too; but England boasts of her foregin missions, on which she spends £2,000,000, while she spends £140,000,000 in drink. I think the poor heathen get more strong drink than Gospel from us.

This is a matter that concerns ourselves very nearly. Many of our young members who have attained their profession at great labor and expense, who have not means or patience to settle down in the better-class neighborhoods, elect to practice in the populous working districts—many of these gentlemen do an amount of work that should be remunerated by £600 or £800 a year, and do not get one-half, because the money goes to the publicans. The late Sir Andrew Clark once stated—"He was often tempted to give up his profession and join in a crusade against strong drink." Medical men are often blamed for ordering drink, and perhaps we sometimes deserve it; but we must take cases as we find them, and a physician's hand should not be bound in the slightest. At the same time, my own belief is that if we had no such liquors as whisky, gin, rum or brandy, but a recognized standard solution of alcohol, labeled alcohol poison and placed on the chemist's shelf, it would answer all requirements and be very little used. However, my case is not against alcohol as a medicine but as a diet. Sir Wm. Jenner struck the right note when he said, "There are times in the crisis of disease, as in the life of a man, when alcohol is useful; but it is as the whip and spur are to the race-horse, it tides over a difficulty by enabling him to put on a spurt, but is in no wise hay and oats."

We come now to the treatment of this disease. Much might be done by the women. If the homes of the artisan and workingman were made more comfortable and attractive, and if the cooking was better, he would not be so fond of the public-house. Man is a docile animal and easily domesticated.

It has often been said that we cannot make a man sober by act of Parliament, but the saying is untrue. Experience has proven that just in proportion as temptation is put in a man's way or out of a man's way does he become drunken or sober.

The grocer's spirit license has done much harm, especially to women. It had already made many of them inebriatess women, especially, should not be expose; to temptation. There are times of physi-

cal weakness which render them an easy prey to drink when once the habit is formed. Women who formerly would not be seen in a public-house cannot now buy their necessaries without being exposed to temptation. The downfall with them is very rapid and the outlook for the children very bad. This law should be repealed.

Finally, there are the two large projects for controlling the trade before the country: The permissive or local veto bill and the Bishop of Chester's scheme on the Gothenburg and Bergen lines. Both have their advocates. Time will not permit me to go into these. I have just touched upon some of the salient points of this great drink question. Some points I have not alluded to—as the insurance aspect, expectation of life, and many others.

This great work—the control of the drink traffic—will proceed. Are we as a profession to be in the van or wake of the movement? In this society there is a large percentage of total abstainers. Others do not see it in exactly the same light as we do, but of one thing I am certain—there is not a single member who would not receive with joy and satisfaction any movement that would emancipate the artisan and workingman from the bondage of strong drink.

SOCIETY REPORTS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of November 28, 1894.

Dr. Robert T. Morris, of New York, by invitation of the Board of Directors, presented

I. DEMONSTRATION OF A MECHANISM OF INTUSSUSCEPTION. II. EXHIBITION OF SPECIMENS ILLUSTRATING EACH STEP IN THE PROGRESS OF INFECTIVE APPENDICITIS.

(See page 45.)

DISCUSSION.

DR. JOHN ASHHURST, JR.: I have listened with a great deal of pleasure to the description of Dr. Morris' specimens, and there are some points that have particularly interested me. What Dr. Morris said with regard to the occurrence of inflammation of the appendix followed by gangrene from pressure, the appendix being a narrow tube, and therefore not able to bear great distention with impunity, is paralleled by what is seen in other parts of the body. We see it in some cases of felon, where the tension becomes very great from the "temporary hypertrophy," as it was called by Virchow. When such a finger is opened, no pus and but little blood may escape, but the whole finger may be apparently packed with dead or dying tissue. This also is an instance of necrosis from tension, due to excessive inflammation where there is no chance for expansion. I have seen the same thing in the testis, where necrosis of a considerable portion of the gland may take place from the firm tunica albuginea preventing expansion of the inflamed organ.

I was also interested in the specimens showing obliteration of the lumen of the appendix. I have seen such specimens. Several weeks ago I removed the appendix of a young lady who for many years had suffered from recurrent attacks of appendicitis, and between the attacks had curious symptoms, referred to the digestive system, which I think were explained by the condition which was found at the operation. In this case the appendix was so much reduced in size that it was with great difficulty it was discovered. It was simply a fibrous band surrounded by serous membrane. No mucous membrane could be seen except a little pouch near its junction with the cæcum.

I was interested in what was said with regard to the causation of reflex symptoms, such as interference with the function of the bowel, which was explained by

a condition of local neuritis. In the case to which I have just referred, the patient had suffered for years with almost continual nausea, though without vomiting. Never did she take a meal without suffering with nausea for hours afterward. I think that the digestive symptoms were explained by the presence of adhesions. The cæcum was closely adherent to the abdominal wall, and it is easy to understand that under such circumstances the nerves of the part would be seriously pressed upon, and neuritis might follow. We find an analogy to this in cases of Littre's and Richter's hernia, where a diverticulum of the bowel, or a small portion of the intestine, is caught in a hernial opening. In such cases there may be grave symptoms of strangulated hernia, though only a small portion of the lumen of the bowel is involved.

Dr. Morris referred to the presence of worms in the appendix. Last winter I operated on a case of acute appendicitis in which, after evacuating a quantity of pus, I saw what I supposed to be an unusually long appendix, but on bringing it out it proved to be a lumbricoid worm loose in the peritoneal cavity, the explanation of its presence being, of course, that it had escaped through a perforation.

Last Saturday I operated on a patient who had been operated on in Brooklyn four years ago for appendicitis, and who supposed that his appendix had been removed. Two years after the first operation the cicatrix had reopened and had discharged a small quantity of pus, and since then a fistula had remained. When he came under my care I advised that the cicatrix should be divided and the part explored, thinking that possibly a silk ligature might be keeping up the discharge. On making an incision, the finger at once entered the abdominal cavity, and I felt a full sized appendix. The case evidently had been one where the surgeon had opened an abscess and very judiciously, in all probability, had not pushed the investigation further. I believe that in many cases of acute appendicitis the safety of the patient depends upon not making too minute an exploration. If the appendix is not readily found it may be permitted to remain. In this case I removed the appendix in the ordinary way, and found it partially obliterated. There were two diaphragms, as it were, making pouches, and in one of these was a pin-hole perforation. The lesson taught by this case is that when it is possible to remove the appendix without too much disturbance, it should be done; but, as I have just said, I believe that there are cases where the line of safety for the patient rests in not making too minute an investigation, and, if the appendix cannot be readily found, in leaving it, and simply evacuating the pus.

Dr. James C. Wilson: Dr. Morris has rather thrown out some suggestive hints with reference to the pathology of appendicitis than gone thoroughly into the discussion of any particular branch of this wide and complex field of surgical pathology. I should have been glad if he had been able to have more fully given us his views in regard to this affection.

I am particularly impressed with what has been said in regard to the remote changes and with the explanation which has been suggested for some of the chronic and troublesome intestinal disturbances which have been so unaccountable in their pathology. I think that we have all been puzzled and have been unable to explain or relieve many cases which probably come within this group of chronic appendicitis, with nerve changes, adhesions and permanent foci of infection, giving rise to persistent disturbance not yielding to treatment. I have had many such cases, which have been classified under the head of chronic intestinal indigestion with nervous symptoms. The difficulty which I find with cases of this kind is to induce them to subject themselves to a surgical operation. In one such case of long standing ill-health, in which Dr. Deaver was associated with me, a diseased appendix was found, and after some months the patient reports that she is greatly improved and has regained her health.

Dr. John H. Musser: I have been particularly interested in the suggestion thrown out by Dr. Morris with reference to the degree of virulence of the symptoms depending upon the character of the infection; that where high fever is an initial symptom the probability is that there is infection with the streptococcus, a form of infection which we know very well is not likely to yield to treatment. We also know that the possibilities of more remote infection are greater, and the liability to

infection of the peritoneum infinitely greater. If in this way we can determine the character of the infection we shall be more guarded in our prognosis and in our treatment. I take it that cases of severe streptococcus infection should be treated early by operation.

I was also interested in noting that in the pathology of appendicitis we see that there are two causes for the symptoms, the one mechanical and the other the septic process, the septic process being responsible for the temperature, the mechanical process being responsible for the pain, for the reflex vomiting, and likewise for the occurrence of further pathological changes, such as gangrene. The specimens readily demonstrate that it is impossible to tell whether or not gangrene is going to take place. We cannot tell from the local symptoms or from the fever whether or not there is going to be perforation. As we well know, some of the simplest cases so far as symptoms are concerned often result in gangrene, and cases may be discharged apparently convalescent when gangrene is going on. I have seen cases operated on at the end of a week or ten days, and there was found gangrene, the presence of which the earlier symptoms had given no indication.

In analogy with streptococcus infection under other circumstances we notice here the tendency to recurrence and the tendency to infection of other tissues. I would ask Dr. Morris if the cases of recurring appendicitis are not largely of streptococcus origin. I have had a case of this nature. If this is the case it is another argument in favor of resort to operation in these recurring cases.

I have had several opportunities to see cases of chronic intestinal disturbance due to continuous infection from the appendix, and the removal of this small focus of infection has proven of the greatest value, resulting, indeed, in the cure of the patient.

Dr. Ernest Laplace: I have been especially interested in the remarks with reference to the relation between the nature of the infection and the temperature. It would be very well, indeed, if such a relation could be established, but I take it that is entirely vain. Even if we were prepared to say that in appendicitis there were only two forms of infection, that by the streptococcus and that by the common colon bacillus, I would be prepared to say that there would be no two patients in whom the reaction to these points would be exactly the same, and that there are some systems on which the ptomaines of the streptococcus have very little irritating effect and produce very little elevation of temperature, and therefore the temperature at no time is a real index of the severity of the case.

Another point was the relation of intestinal symptoms—intestinal atony to the possible degree of nerve fixation by fibrous tissue resulting from chronic inflammation. I am sorry that Dr. Morris did not tell us the results obtained in the cases referred to. My experience in the removal of scar tissue not only from this part but from other regions, and especially where serous membranes are involved, is that the reproduction of scar tissue is as rapid as before, and I should doubt the wisdom of disturbing strong fibrous adhesions, which merely result in a little nerve disturbance in the intestine, in order to relieve that condition. We all know that once nature has done the work for us, we should respect that work, because she has done it better than we could. If we remove this fibrous tissue we leave a surface which must granulate and form new fibrous tissue, and the result is the same as before, the same nerves are apt to be affected, and the patient is as bad off, plus the danger of the operation.

The specimens show that Dr. Morris has gone deeply into the philosophy of the subject, and the points brought out in the surgical pathology of this affection are interesting and solve many points which have been problems with me.

Dr. John B. Roberts: I should like Dr. Morris in closing the discussion to tell us what evidence he has that neuritis exists in the cases mentioned. The doctor has not gone into the subject of the operative surgery, but has confined himself to the portion which is the more important at this time, namely, the pathology. I would be glad to have him tell us whether in his operative work he goes upon this principle of a possible neuritis and secondary digestive trouble due to the retention and binding down of the appendix. Does he always make a search for the appendix in the primary opera-

tion, even where there is a great deal of pus, or does he evacuate the pus and wait for a subsequent period to remove the appendix? I would also ask if in operations where a short stump has been left he has seen evidences of digestive trouble from fibrous contraction, or whether neurotic symptoms are found only in cases cured by nature?

DR. JOHN B. DEAVER: There are only one or two points to which I shall refer. The first is the separation of the appendix, to which Dr. Morris has referred, where we find the stump and then the tip of the organ at some little distance. I have met with a similar condition where the tip of the appendix was the source of the infection. In one of these cases the tip laid behind the colon and contained an abscess.

The pain in chronic appendicitis I have no doubt is due to neuritis in certain cases. I also believe that it is due to traction made on the adhesions. I think that this is particularly true after operations where we are called upon to remove stumps, and it should make us more careful in treating stumps. Where it can be done the stump should be invaginated and the serous coat of the cæcum stitched over it. The nerves reach the appendix through the mesappendix, and where the mesappendix is not greatly infiltrated we should eliminate the element of neuritis and look for some other explanation. I believe, therefore, that in these operations followed by severe pain, which is referred to the right iliac region and aggravated by certain motions of the body, it is warrantable to reopen and examine the stump of the appendix, if we can find no other explanation for the pain.

Gangrene of the mesappendix I have seen in a certain number of cases. In one such case the mesappendix was gangrenous, while the appendix was practically intact, the operation being done very early. I might mention a case of abscess of the appendix. This man had but few symptoms either general or local. It was suggested to him that he had appendicitis, and he at once agreed to operation. The appendix was perforated at its mid-point in the line between the two layers of the mesappendix, making the abscess, which contained half a dram of pus, extra-peritoneal.

With regard to streptococcus and colon-bacillus infection, I believe that the streptococcus is the more virulent, and I believe also that this plays a *rôle* in certain of the cases with high temperature. It is not the cases with high temperature that I fear. It is the cases with moderate fever that are apt to deceive us. I place little reliance on the temperature, but am governed by the local condition, the presence of peritonitis, and by progressive invasion of the peritoneal cavity.

The results of operation, so far as my experience goes, have been very satisfactory. I have not found reflex disturbance follow removal of the appendix where I was to dispose of the stump in the ideal way. Where this has not been possible, on account of dense adhesions, or on account of the fear of breaking down the limiting wall which nature had thrown out, I have seen pain follow which in some cases was subsequently demonstrated to be due to adhesions.

DR. G. G. DAVIS: I would ask Dr. Morris what is his view as to the relation which infection bears to appendicitis? In other words, if there is one form termed infective, what other inflammations of the appendix are there? Infection has been said to be a cause of intestinal catarrh. May the process also be a reversed one? Does the doctor recognize such a thing as a catarrhal process being a cause of appendicitis?

DR. M. PRICE: I should have liked if Dr. Morris had taken up more than the pathology, as those of us who are doing operative work care very little about the pathology of appendicitis; we care more about the condition found at the time of operation. I recognize two entirely different conditions with which we have to deal, one where the bowels are confined and it is impossible to move them, and the other where the bowels can be readily moved. These conditions are to be dealt with differently, although both are from the same original cause.

As regards temperature: in 23 abdominal sections for appendicitis, with 19 consecutive recoveries, I have never seen but one case where the temperature was below normal. In looking over the report of Dr. Keen's cases, in a paper in 1891, I note that in two-thirds of them the temperature was below normal. I notice the same thing in the reports of other operators; the temperature is below normal at

the time that the case comes into the hands of the operator. Of course, in the cases that come into my hands, the disease had existed from twenty-four hours to three or four days, and there has been time for pus to form.

There is no question that there are nervous symptoms caused by pressure upon nerves. This is sometimes seen after amputations where resection of the nerve may subsequently be required. I have seen it beautifully illustrated in a case recently in Dr. Joseph Price's hospital. The patient was unable to walk when admitted. Both appendages were removed, it was supposed close to the uterus. It was a dirty case, requiring drainage. After recovery she still complained of pain in the right iliac fossa. On reopening and excising the right stump it was found that the ligature had not been encapsulated, and four or five drops of pus were in the stump. This was removed and the part curetted, and in six weeks the patient could walk as well as any one.

I know that Dr. Morris believes in clean surgery and in complete surgery, and I would ask if he would be willing to leave in the pelvis such a mass as Dr. Laplace refers to, and hope for perfect results. I do not see where Dr. Laplace gets his data when he says that the same fibrous condition exists after you have removed the offending cause.

I would ask Dr. Morris in regard to the mortality, in view of the fact that in the Johns Hopkins Hospital they have had eight deaths in nine operations. Christian Fenger reports eleven consecutive deaths in appendicitis operations. I believe that all these cases ought to get well unless they are practically dead at the time of operation. The radical men who believe in surgery are to-day saving nine out of ten of the cases that formerly died. I believe that the reason of the deaths is that complete operations are not done. I agree with Dr. Ashhurst, that if the bowels are soluble and there is an abscess, the only thing to do is to open and drain, because the patient will get well. I believe that all deaths after operation are due to bad judgment or to bad surgery —the man either operates on a dying patient or he does bad surgery.

Dr. Joseph Hoffman: I think that it takes only a few such specimens as have been shown to convince us that appendicitis is naturally a surgical disease. Clinicians generally consider this affection in the light that they formerly regarded tubal and ovarian troubles, but when specimens began to be circulated and the condition of the tubes to be seen, the propriety of operation was no longer a question, and it was acknowledged to be distinctly a branch of surgical work. There is a parallel between the tube and the appendix, and the pathology of the appendix is the same as in the Fallopian tube.

I always smile when I hear about this wonderful power of nature, for much of our surgery is done to cure the failures of nature, and this is particularly true in the case of the appendix. The conditions about the head of the colon are such as we would not tolerate in any other portion of the body. If they were in the duodenum the surgeon would at once interfere. Why should it be allowed to remain in one place and removed in another?

We know the reflex troubles that adhesions of the tubes and ovaries may cause. We may have any number of reflex symptoms. These same conditions are found in appendicitis. If adhesions of the bowel will cause trouble in the neighborhood of the duodenum they will also in the region of the cæcum. It is no more surgical sense to leave them in one place than in another.

Dr. W. Easterly Ashton: The theory that every case of appendicitis is an infectious case is a long step toward a knowledge of its pathology. No matter what may be the exciting causes, all these inflammations must be accepted as due to infection. The appendix is normally occupied with feces in a more or less fluid state, and it must therefore contain bacteria, so that any existing cause of inflammation must at once be followed by infection. It has been demonstrated that it is not necessary to have perforation, or even ulceration, of the wall of the appendix or intestine to permit migration of bacteria. This has been shown by constricting the intestine of a rabbit with a rubber band, when, as soon as stasis is produced, bacteria migrate. It has been further shown that these bacteria under normal conditions produce no trouble, but when there is any interference with the circulation of the appendix, or any want of integrity in its wall, these bacteria not only penetrate the tissue, but perforate the wall com-

pletely and escape into the peritoneal cavity. All of these cases, no matter how mild, are infectious. The fact that the appendix is a rudimentary and unused organ is a constant predisposing cause to attacks of inflammation, for we know that the retrograde changes occurring in an unused organ make it especially susceptible to inflammatory attacks.

Again, the anatomical position of the organ renders it liable to dragging and strangulation. Situated as it is at the head of the colon, with a small mesappendix and a single arterial supply, distention of the large bowel or ileum will drag upon the appendix and induce nutritive changes favoring the migration of bacteria.

I believe in time all of us will agree that in appendicitis we are dealing with a septic affection, and when we do agree to this, then the knife will be used in all cases so soon as the diagnosis is clear, whether the case is an acute or chronic one.

THE PRESIDENT, DR. DE FOREST WILLARD: I would ask Dr. Morris how long he thinks it necessary that the septic process should exist before we may have secondary abscesses. This question came up in the Pathological Society on the presentation of the specimen of abscess of the liver which has been shown to-night. It was held by some that the abscess of the liver was probably not due to the diseased appendix, because it occurred within five days of the appendix trouble. I have seen three cases in which secondary abscess occurred within three days.

That these cases of appendicitis are infectious has been demonstrated by the large number of specimens shown to-night.

DR. MORRIS, of New York City: It is not safe to assume that any particular case of chronic intestinal indigestion is due to the appendix, unless on palpation we can determine that the appendix is probably the center from which the trouble proceeds. In most patients it is not difficult to palpate the appendix. I do not know what proportion of cases of intestinal indigestion is due to chronic infection of the appendix, but I know that some are, and these should be subjected to proper treatment, which I believe to be surgical.

With regard to temperature, as I have stated, my impression is that high temperature at the outset usually occurs with mixed infection or streptococcus infection. I think that the results of such infection are apt to be confined to the vicinity of the appendix for the first few days. With the insidious infection with the colon bacillus we are apt to have a temperature of 100° with a pulse of 120. Such a condition is more serious than a temperature of 105° with a pulse of 120. When the vital signs fall apart, look out. The general practitioner cannot tell *à priori* whether a patient is to be entirely well or entirely dead in three days from the beginning of any attack of appendicitis. This cannot be determined in advance, because the extent of the invasion of infection in any given case is not to be estimated. Our surgery has been making progress. If we cannot show physicians by our surgery and our statistics that these cases ought to be operated on, we should not operate. I believe that to-day, however, we have an almost perfect operative technique in dealing with most forms of appendicitis.

Dr. Laplace believes that no two patients will react alike to the same infection. I also believe that, but if the temperature is high we are apt to have a mixed infection or infection with streptococci. That I have determined by cultures from those cases where the temperature was high. All of the points brought forward to-night were pretty well proven by my work before being presented.

Dr. Roberts asked in regard to the evidence of neuritis. This was found in the direct examination of the nerves. These specimens have been examined by my pathologists and the evidences of sclerosis found. I have had one case when I operated for a stump that had been left. The patient suffered with neuritis, chronic constipation and digestive disturbances, and had been an invalid for a long while. I removed the stump, and the patient made an excellent recovery. The bowels move regularly; he is free from pain and has gained in weight. Another gentleman was compelled to give up his work as a professor on account of irritation in the fibrous remains of an appendix. This was removed, and he returned to his normal condition. A physician who had been a nervous, dyspeptic individual for many years came to me with an appendix which had lost much of its structure. It contained a few fibers of sclerosed nerves. We removed this appendix and

separated the adhesions, and he is now a completely changed man. I could enumerate other cases.

I have avoided the question of operation because it is such a large one. As regards my own statistics at present, I feel inclined not to quote them, for it would savor of boasting. I may say that in a pretty large number of cases operated on while infection was limited to the appendix, and in the interval between acute attacks, I have had no deaths and nothing which seemed to point to a bad result. I cannot look forward to death in a case of this sort. Surgeons have developed an operation which is less to be feared than a single attack of appendicitis.

I have never seen catarrhal appendicitis. I have operated in cases where this diagnosis has been made, but I have never seen the affection. There is no doubt that catarrhal inflammation of the mucous membrane may occur, but I doubt if it ever gives rise to symptoms.

I believe with Dr. Price, that it is better to do a pretty radical operation where we start in to remove the infected mass. I do not feel like leaving such a mass after having looked at it. My statistics, which will be published before long, will give an analysis of my results. We save most of our badly infected cases to-day. Cases in which I think a short time ago my mortality rate would have been 50 per cent., I believe will now give a mortality of less than 10 per cent. These are the cases with pus, wide infection and peritonitis.

As Dr. Ashton has said, bacteria may be present and no trouble arise until an infection atrium occurs, when the bacteria at once migrate. This may be caused in various ways; for instance, dislocation of an appendix from its particular position is very common. The individual may be struck by the elbow of a friend, or in certain manipulations the appendix may be displaced. It may not go back to its original position; it may be twisted on its mesappendix. Its contents are locked in and there may be a little discomfort, lasting a few hours. All at once bacteria begin to migrate because the mucosa has undergone necrosis from twist pressure. This dislocation of the appendix is very common, and is usually a matter of no importance to the patient. I also believe, as Dr. Ashton has said, that the appendix is more readily attacked by bacteria because it is a rudimentary structure, just as some wisdom teeth are more liable to decay on this account.

As to the length of time between the beginning of infection and the occurrence of liver abscess, I cannot say. I can only say this, that within forty-eight hours of the beginning of an attack of appendicitis I have found thrombi in the veins of the mesappendix which could have caused the beginning of a liver abscess on that day. I do not see why we might not have abscess of the liver within two or three days of the beginning of an attack of appendicitis.

Kerosene in Alcoholism:

The most recent remedy for alcoholism in Russia is petroleum or paraffin oil, to which the notice of the St. Petersburg medical authorities was called by accident. It appears that a laboring man who had been drinking heavily for four days and nights entered, in a complete state of intoxication, a grocer's shop. Unnoticed by the shopkeeper, he staggered up to an open cask of petroleum and began drinking from it. It is related that the petroleum cured him of all the effects of over-drinking; the nausea, unsteadiness of gait and headache disappeared as if by magic.—*N. Y. Med. Times.*

Thioform.

Thioform, a chemical combination of bismuth, sulphur and salicylic acid, has been brought forward as a substitute for iodoform. It is a tasteless and odorless powder of a greenish-yellow color. When used as a dressing for ulcers, wounds, burns, etc., thioform has shown itself to be equal, if not superior, to iodoform. However, the specific action of iodoform in tuberculous affections could not be expected from the use of thioform, as the latter does not contain iodine. Finally, thioform has been used internally in doses of fifteen grains. Its action was similar, but superior, to bismuth salicylate.—*Texas Courier Record.*

Ice (*N. Y. Med. Times*) applied to the external genitals (the scrotum in men and the labia majora in women) controls epistaxis and hæmoptysis.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY

for October. Dr. A. Van DerVeer, of Albany, N. Y., contributes a

Report in Abdominal Surgery,

being an analysis of one hundred and forty-five cases done upon the ovaries and uterine appendages, with special remarks as to preparation of the patient, place of operation, use of drainage, treatment and results. In the series of cases there have been seventeen deaths, in one of which the autopsy revealed the pelvis and abdominal cavity full of clots, some undergoing septic change, but no pus present, nor had there been any evidence of distention of the abdomen or any condition to indicate true peritonitis. Death had occurred on the fourteenth day, with no serious symptom presenting at any time, excepting a rapid pulse for a period of nearly three days previous to death. On careful examination of the pedicle the ligature had evidently slipped, and the author regrets that a drainage-tube was not used in this case, as in that way the hemorrhage would have been detected. The operation was for simple uncomplicated ovarian cyst.

The author emphasizes the importance of regulating the bowels and proper attention to such diet as does not constipate previous to operation. He also lays stress upon a careful examination of the urine. The previous habit of the patient in regard to the use of morphia should be carefully inquired into, and is not a contraindication to operation, but the same will necessarily be needed after and without fear in giving as full doses may be required to control pain. In regard to the preparation of the operating-room, the author states that he has long since given up the use of the carbolic spray and relies upon strict cleanliness, washing all woodwork, walls and floors with bichloride solution. A large proportion of the cases reported were operated upon in the amphitheater of the Albany Hospital, and some in the presence of one hundred and fifty or more students. The author emphasizes the importance of a short incision.

He is a firm believer in the drainage-tube. In regard to suture material he prefers silkworm gut, and states that with this he seldom has a stitch-hole abscess. As to the time of removing the stitches, it is well if the superficial ones are removed at the end of the second day or during the first dressing of the wound, and then the deep ones are best left until about the tenth day. They do no harm and certainly help to keep the abdominal incision in more perfect apposition. In conditions of continued oozing from adhesions, and where the abdominal walls have been greatly stretched by the size of the tumor, he has seen in two of his cases a most happy result from folding the abdominal wall over, having previously put in through-and-through sutures of silkworm gut, taking them out at the end of forty-eight hours.

As to the dressing of the wound, he has uniformly employed the powdered iodoform, then the iodoform gauze, with the Gamgee pads and flannel bandage, doing the first dressing at the end of forty-eight hours, removing what is usually but soiled iodoform gauze, reapplying the second dressing and letting it remain until the wound is healed, except in cases where the drainage-tube may have produced some soiling.

In those cases where the stump seemed to flatten out over the ligature the author brings the peritoneal surfaces together with two or three interrupted sutures of fine silk, and believes that this has some effect in obviating intestinal obstruction due to a coil of bowel becoming adherent to the stump of the pedicle.

As to the pulse and temperature, he is satisfied that the former is of far more importance than the taking of the latter. The heart's action plainly tells of serious trouble going on in the way of intestinal obstruction or of either form of peritonitis, while there are many conditions, really non-essential to the recovery of the patient, that will cause an increase in temperature apparently alarming.

The author enters a vigorous plea against tinkering and deferring surgical advice till too late.

C. C. Frederick, M.D., Adjunct Professor of Obstetrics, Medical Department Niagara University, Buffalo, N. Y., discusses

The Relations of Renal Insufficiency to Operations.

He draws the following conclusions:

1. Every patient's urine should be examined quantitatively and qualitatively before operation if possible.

2. Minor degrees of renal insufficiency and minor degrees of renal lesions are not contraindications to operations.

3. The graver forms of renal disease are contraindications to operation except it be for disease or growths which have a causal relation to the kidney disease.

4. Patients are more liable to shock and slow convalescence after operation when suffering from kidney disease.

5. Patients may develop acute renal congestion *de novo* after operation and are especially liable to do so if there have been old lesions.

6. That there seems to be little choice between chloroform and ether as the anæsthetic in renal insufficiency, both alike producing congestion.

William B. Dewees, A.M., M.D., of Saline, Kan., contributes an article on

The Care of Pregnant Women.

The author believes that the next advance in obstetrical science will be the bringing home to the general practitioner of the fact that the diseases peculiar to women during pregnancy and parturition are very largely preventable. The paramount duties of the obstetrician in the study and care of pregnant women may be classified as follows:

1. To discover if the patient be actually pregnant

2. To determine positively if the impregnation be uterine or normal as contradistinguished from tubal, abdominal and abnormal pregnancy.

3. To carefully note the pregnant woman's history, including her age, primiparity or multiparity, environments, station in life, general condition of health, period of gestation, as well as her dress, food, drink and habits of life. To make repeated examinations of the urine and ascertain the temperature from the time pregnancy is established to the termination of gestation.

4. To make a physical examination for the purpose of accurately determining the diameters of the pelvic straits; the symmetry and size of the bony outlet; the integrity, condition and position of the vagina, uterus and other intrapelvic viscera and adjacent structures; the state of the abdominal muscles; the presence or absence of hernia, varicose veins, tumors, etc.; the shape, size and condition of the breasts and nipples; the condition of the heart, lungs, mind, stomach, bowels, etc.

5. To observe the state of the fœtus, its strength and viability, as well as the implantation of the placenta.

The physician should insist upon the following on the part of his patient:

1. Absolute, regular hours and wholesome environments.

2. Plain but nutritious and wholesome food and drink, being principally composed of fresh lean meats, fresh fruits, pure milk and distilled water.

3. A proper amount of exercise, by walking or light labor on foot, and maintaining the correct erect posture. Whenever infirmity forbids such exercise, recourse should be had to massage, and as much time passed in the open air as is advisable under such unfortunate circumstances. Rest in the recumbent posture after meals and fatiguing efforts, with not less than ten hours' sleep out of every twenty-four.

4. An open condition of the bowels and skin, which is to be chiefly maintained by proper diet, exercise and bathing, the wearing of flannels, warm low-heeled shoes and loose garments, and in rare cases the proper use of laxatives and hot-water enemas.

The author believes that the term puerperal fever should be expunged from medical literature and be replaced by the proper term, parturial sepsis.

In regard to ectopic pregnancy, the author considers that there is but one method of treatment—abdominal section and the removal of the product of gestation so soon as the condition is discovered.

Where there exists a contracted pelvis he believes that the life of the fœtus should not be sacrificed, but the gestation allowed to go on to term and the woman delivered by Cæsarean section or symphyseotomy. It is the duty of the obstetrician, therefore, to familiarize himself thoroughly with the indications as well as the technique of both these operations, neither of which is to be lightly undertaken by any one who does not possess the requisite skill both in the obstetric art and abdominal surgery.

In dealing with placenta previa at term the writer prefers to bring the head down at once with the forceps, tamponing the uterus by this means. He prefers the use of the forceps to the hand. As soon as the diagnosis is established action must be prompt in evacuating the uterine contents. Hemorrhage is the danger signal. When this occurs prior to the sixth month we should proceed without any regard to the life of the child. After this time we should proceed as promptly, but with all possible endeavor to save the lives of the mother and child. The cervix should be dilated with the fingers made antiseptic and with the patient under anæsthesia until there is sufficient dilatation for the application of the forceps. When the dilatation is greater and the position abnormal or less favorable the accoucheur had better resort to the passing of the hand and turning by Braxton-Hicks method and drawing the child into the cervix, and thus arrest the hemorrhage.

Should Antiseptic Vaginal Douching be Made a Routine Practice During the Puerperium?

is the title of a paper by Adam H. Wright, M.D., of Toronto. The author is opposed to its use for the following reasons:

1. Douching disturbs that perfect quiet and rest which are so desirable for a patient after labor. He does not refer to surgical rest of the wounded tissues, but to rest in a general way, which is so delicious to a weary and more or less exhausted woman.

2. Douching is unscientific on surgical grounds. After labor the utero-vaginal canal is bruised and wounded. On surgical principles the most important points in the treatment are rest, position, pressure and drainage. The wounds of the cervix and vagina are, as a rule, kept closed by the elastic and even pressure of the surrounding tissues. The introduction of suppositories and douching seriously interferes with rest and pressure and, in the author's opinion, materially delays the healing of those wounds. The recumbent posture, with the slight changes in position required for voiding urine and fæces, is well adapted for drainage.

3. Douching does not lessen the dangers accruing from the presence of bacteria in the vagina, since vaginal antiseptic injections may change the normal acidity of the secretions and thus chemically lessen the resistance of the tissues to bacteria.

4. Douching is actually dangerous. It is apt to disturb clots and thus open avenues

for infection; to open lacerations of the cervix and vagina and thus prevent them from healing; to wash bacteria into the uterine cavity and thus cause septic endometritis. Among other dangers which are generally due to accident or carelessness are the introduction of septic matter by fingers or instruments.

The author is strongly impressed with the opinion that the use of the douche does sometimes, if not frequently, cause a rise of temperature which must, of course, be looked upon as an evil.

The editorial in this issue deals with "Ocular Affections of Uterine Origin."

Augustus P. Clarke, M.D., of Cambridge, Mass., contributes a paper on "The Relation of Hysteria to Structural Changes in the Uterus and its Adnexa." This article has already been reviewed in THE MEDICAL AND SURGICAL REPORTER for November 3, 1894, page 628.

In the Department of Pædiatry Henry Howitt, M.D., of Guelph, Ont., contributes

Remarks Bearing on the Surgical Treatment of Intussusception in the Infant,

reporting two successful cases. As the result of his experience the writer presents the following conclusions:

1. The diagnosis in infancy is not difficult, for the reason that obstruction of the bowel by any other cause is extremely uncommon, and when it does exist is sure to be owing to congenital defects or as readily recognized ailments. The sudden and pronounced nature of the onset, the presence of more or less evidence of shock, followed shortly by vomiting, paroxysmal colic and marked tenesmic efforts, which give rise to non-fæcal passages of blood and slime in a child previously healthy or who has a catarrhal affection of the bowel, render the diagnosis for all practical purposes complete. If in addition to these we can detect an oval tumor in line of colon no room for doubt is possible. In consequence of the pliable condition of abdominal walls at this early age a lump the size of a pigeon egg can, in the absence of tympanites, be readily felt by the educated hand.

2. The operation should be performed early and not when the powers of life are ebbing away. Within twenty-four hours of the commencement of attack, and in the absence of marked tympanites, an attempt under chloroform probably should be made by distention and taxis; but this trial should be neither forcible, prolonged nor repeated, and failing, an abdominal section should immediately follow. In the second day and later the operation should be done without a moment's unnecessary delay. The operator should have a practical knowledge of aseptic surgery as applied to abdominal work.

3. The incision should be made in the median line, either above the umbilicus or lower, according to the position of the lump. When the tumor cannot be defined let the middle of incision be at the umbilicus, for through this the part, after evisceration, no matter where situated, may be reached and brought into view. The wound need not be more than from three to three and a half inches in length. The pliable nature of the abdominal walls and the smallness of the cavity render complete exploration with fingers quite easy.

4. Evisceration will be found not only to save time, but to aid very much in facilitating the after-steps of the operation, for it allows more room and permits the large bowel to be readily brought out. The author differs from those who state that it is more dangerous to expose the intestines in infancy than in later life. The eviscerated contents of abdomen should be protected by suitable cloths wrung out of hot water and applied in layers, the outer of which are changed when necessary, or the heat maintained by irrigation with water at a temperature of 92°.

5. Reduction is probably best accomplished by making pressure on the apex of the intussusceptum, while at the same time the intussuscepiens are pulled in an opposite direction. In some instances it is better to break with a probe or other instrument the adhesions at neck and then to make firm pressure on the intussusceptum by grasping the whole mass with the hand before an endeavor is made to reduce it.

6. Before the reduced portion is returned to abdomen the operator should not only demonstrate that the obstruction has been completely removed, but should also empty the contents of ileum into large bowel. The last may easily be done by gently stroking the ileum downward with a soft sponge. The removal of the material from above the place where the obstruction existed performs important work for an organ the functions of which are impaired, and it also greatly hastens the expulsion of offensive and septic matter from the body.

7. The replacement of the small intestines may be facilitated by the surgeon and assistant hooking two fingers of their left hands into opposite sides of the wound and then lifting the lower portion of the body from the table. Should the intestines be unusually distended with gas, it is the author's opinion that there is no objection to multiple punctures with clean hypodermic needles.

8. A point which also applies to most abdominal operations is arrangement of omentum. By spreading the omentum over the bowels it certainly prevents adhesion of the gut to the line of incision. The lymphatics of it are admitted to be endowed with more than ordinary power of absorption, and by extending to seat of impairment may in no small measure prevent trouble. The omentum may also haply become attached to a weak point on the affected portion of the bowel, and thus be an agent in preventing perforation.

9. The wound should be sealed in such a manner that the urine of the child cannot possibly reach it.

The author states that in all six cases of intussusception have come under his personal observation—four in the infant and two in the adult Three were treated by abdominal section and recovered, and three by non-operative means, with one result—death.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Relation of Uric Acid to Urea on Different Diets.

According to Ritter, the relation of the uric acid to the urea on a normal diet is 1:36; on a mixed diet, 1:27.5; on a vegetable diet, 1:22. From this it appears that a person subsisting upon a mixed diet eliminates 25 per cent. more uric acid than a person whose diet is vegetable in character, while the person whose diet is exclusively of an animal nature eliminates more than 60 per cent. more uric acid than a person whose diet is vegetable. This fact, taken in connection with the well-known prevalence of gout among beef-eating Englishmen, is very significant. The facts developed in the physiological laboratory are showing us more and more clearly from year to year the folly of subsisting upon a second-hand diet. The poisons derived from the flesh of lower animals through flesh-eating are doubtless responsible for a vastly greater number of disorders than we are at present aware of.—*Mod. Med.*

Apex Expansion in Phthisis.

Weaver (*N. Y. Med. Jour.*) recommends after a full inspiration to hold the breath for a moment by closing the glottis. The effect is increased if, during the holding of the breath, the lower chest is compressed with the hands. After a few weeks the inspirations become much fuller and the tension developed greatly increased. The arms should be raised in order to get the fullest inspirations. These efforts at forced expiration should be continued for ten to fifteen minutes every two hours during the day—before arising in the morning and after retiring at night. The patient should be under constant medical supervision, and at first the efforts must not be too violent. During hemorrhage and for a week after it is completely stopped, pulmonary gymnastics should be suspended. To overcome muscular atrophy about the chest and to increase its expansion, the patient may learn the use of Indian clubs and dumb-bells and resort to them regularly.

Bismuth in Gastric Disease.

Matthes has investigated, both experimentally and clinically, Fleiner's method of treating irritative diseases of the stomach with large doses of bismuth. The results of the treatment were very successful, especially in lessening pain. From experiments on dogs the author shows that ten to twenty minutes after ingestion the bismuth sinks to the bottom of the stomach, whereas several hours later it is found spread over and fixed to the stomach wall, becoming intimately mixed with mucus. Even with a full stomach a large portion is found similarly deposited. Against the action of chemical agents on the stomach wall this deposit of bismuth is most resistant. In men shortly after the ingestion of bismuth the water used for washing out the stomach returns clear, but if later the stomach contents be expressed, bismuth with mucus is removed. Experimentally, bismuth is shown to increase the secretions of mucus. To determine the action of bismuth in cases of erosion, etc., of the stomach, defects were made experimentally in the stomach mucous membrane of dogs and rabbits, and bismuth was then administered. In some cases the results were very indefinite, but in two experiments positive results were obtained. In one case an adherent crust was found acting as a protection to the defect, and sections from both cases showed healing ulcers. In the case of the crust, bismuth crystals were found in the granulation tissues of the healing ulcer. No symptoms of bismuth-poisoning occurred. Experiments thus show that bismuth adheres to the defect in the stomach wall and that healing may take place in a crust so formed; this crust, however, is not always present. Comparison with control animals showed that in those treated with bismuth the defects healed more rapidly. Digestion can go on while the bismuth deposit is present, although in artificial digestion the pepsin is carried down by the bismuth, and in this way digestion is hindered. The author says that both experimentally and clinically Fleiner's method of treatment is practically and theoretically correct, with the exception of the question of position (in reference to the site of the ulcer), which he shows not to have any influence in regard to the subsequent disposition of the bismuth.—*Brit. Med. Jour.*

Lesions of the Stomach Simulating Cancer.

In Paris lately M. Ferrier drew the attention of his colleagues of the Surgical Society to a form of gastric disorder simulating cancer, and which was much ignored in a surgical point of view in France. A woman entered the hospital with gastric troubles, presenting all the symptoms of cancer and coinciding with the existence of an epigastric tumor. M. Ferrier performed laparotomy for exploring purposes, and found the stomach adherent to the walls of the abdomen and to the left lobe of the liver. After breaking down those adhesions the operator closed the wound, and the patient gradually lost all bad symptoms and left the hospital quite recovered. In concluding, M. Ferrier said that in many cases purely inflammatory lesions could simulate cancer, and an exploring operation would put the case in its true light and do no harm to the patient.—*Med. Press and Circular.*

Rapidly Fatal Atrophic Gastritis.

M. Rosenheim recently reported to the Berlin Medical Society the case of a woman, fifty-eight years of age, who had presented the symptoms, together with the physical and functional signs, of cancer of the pylorus. The patient had been in good health until March, 1893, when she was attacked by gastric troubles, which very rapidly attained a considerable degree of intensity. The loss of appetite, nausea and vomiting were so marked that at the end of fifteen days the patient was unable to leave her bed. Upon examination there were found a small tumor in the pyloric region and slight dilatation of the stomach, an absence of hydrochloric and the presence of lactic acid in the gastric juice. The woman died in June with an appearance of emaciation and cachexia. At the autopsy made by Professor Virchow no cancerous tumor was found. What had been taken during life for a neoplasm was a simple thickening of the muscular layer. The mucous membrane was completely atrophied, and it was probable that to this atrophy death should be attributed. The case is of interest from the double point of view of the mistaken diagnosis, though all the symptoms pointed to carcinoma and its rapid course.—*La Tribune Medicale.*

Puerperal Eclampsia.

Doderlein (*Munch. med. Woch.*) first refers to the deficient knowledge of the causation of this disease and to the want of success attending its treatment. There have heretofore been two lines of treatment, the medical and obstetrical. The morphine treatment can hardly be said to have been successful. Treatment by bleeding, along with infusion, hot baths, etc., has also been ineffectual. The question arises as to whether these cases should be treated with morphine, chloral hydrate, chloroform, and the labor left to itself, or whether delivery should be artificially hastened. If the conditions are favorable to the extraction of the child delivery should be completed, otherwise forced delivery may be a severe procedure. Duhrssen showed that forced delivery under deep chloroform anæsthesia brought the convulsions to an end. If the cervix is dilated to about the size of a two-shilling piece extraction can be practiced by the aid of a few incisions. Where incisions would produce too great an injury, Duhrssen recommends dilatation with the kolpeurynter. The treatment adopted by this author has yielded improved results. Owing, however, to the difficulty of carrying it out in practice and to the risks of infection, Cæsarean section has been proposed. In 19 collected cases of which details are given here, 8 died. Among these 1 succumbed to apoplexy, 1 to general tuberculosis, and 3 others were moribund on admission. In only 1 case did the eclampsia remain uninfluenced. Thus the operative treatment certainly has a favorable influence on the disease. In a primipara, aged forty-four years, with a conjugate of 8.5 cm., Cæsarean section was performed by the author with the best results. No further fits occurred after it.

Lady Mary Wortley Montagu on Inoculation.

In an article in the *Popular Science Monthly* Mrs. Plunkett quotes the following account of small-pox inoculation from Lady Mary Montagu's letters: "Apropos of distempers, I am going to tell you of a thing that I am sure will make you wish yourself here. The small-pox, so general and so fatal among us, is entirely harmless here by the invention of ingrafting, which is the term they give it here. There is a set of old women who make it their business to perform the operation in the month of September, when the great heat is abated. People send to one another to know if any of their family has a mind to have the small-pox. They make parties for the purpose, and when they are met—commonly fifteen or sixteen together—the old woman comes with a nutshell full of the matter of the best sort of small-pox and asks what vein you will please to have opened. She immediately rips open the one that you offer to her with a large needle, which gives you no more pain than a common scratch, and puts into the vein as much venom as can lie upon the head of her needle, and after binds up the little wound with a hollow bit of shell, and in this manner opens four or five veins. The Grecians have commonly the superstition of opening one in the middle of the forehead and in each arm and on the breast, to make the sign of the cross; but this has a very ill effect, all the wounds leaving little scars, and is not done by those that are not superstitious, who choose to have them in the legs or in that part of the arm that is concealed. The children or young patients play together all the rest of the day and are in perfect health till the eighth; then the fever begins to seize them and they keep their beds two days, very seldom three. They have very rarely above twenty or thirty in their faces, which never mark; and in eight days' time are as well as before their illness. Where they are wounded there remain running sores during their distemper, which I doubt not is a great relief of it. Every year thousands undergo this operation, and the French ambassador says that they take the small-pox here by way of diversion, as they take the waters in other countries."

Treatment of Cystitis in the Female.

According to Dr. J C. Hersler (*University Med. Mag.*) the indications for treatment are as follows:

1. To remove any discoverable source or sources of irritation which act through the medium of the urine. This may be effected by a milk diet and a discontinuance of the use of acids, pepper, etc. Any mechanical source of vesical irritation should receive appropriate treatment.

2. The urine should be rendered bland by the use of a milk diet, the ingestion of considerable quantities of water, the administration of potassium citrate if the urine be too acid or of boric acid if it be alkaline.

3. Pelvic congestion should be relieved by

hot vaginal douches, placing the patient in the knee-chest position, and the correction of constipation.

4. The inflamed cystic mucous membrane may be relieved by the administration of boric acid, ol. santali, copaiba or cresote by mouth; or the use of injections of boric acid, carbolic acid or nitrate of silver in suitable strengths.

5. The patient's general health should be improved by tonics, etc.

6. Rest in bed, especially in all acute cases, is absolutely imperative.

While advocating direct local treatment for cases of cystitis which do not readily respond to ordinary therapeutic measures, the writer advises that it should be employed with judgment and caution.

Two New Signs of Dilatation of the Stomach.

It is not difficult to diagnose gastrectasia when it has attained any degree of development, but at the inception of the affection the difficulties which beset the physician are many. Many of the methods of diagnosis are impracticable in private practice. M. Aufrecht directs attention to two new signs obtained by percussion. In percussing a stomach which has commenced to dilate, by means of a pleximeter, one obtains at certain points in the gastric region a dullness more or less complete in lieu of the usual tympanitic tone. If the pleximeter is kept at the point of dullness and feeble percussion is made, after waiting a few seconds the dullness will be found to have been replaced by a tympanitic tone. This phenomenon is explained by contraction of the walls of the stomach on account of hypertrophied muscular coat which is constantly present in gastrectasis. The second sign is a cracked-pot sound which is obtained in the immediate vicinity of the dullness already described.—*Sem. Med.*

The Treatment of Typhoid Fever.

Lee (*Chicago Med. Rec.*) thus formulates his treatment of this formidable disease. Without waiting for the development of typhoid fever the very first proposition is to make the patient surgically clean. The bowels are drenched with a copious douche of water, either plain or soapy, until the water returns as clean as it enters the bowel. Bathing is performed at regular intervals. The patient is put in a cold pack to reduce the temperature. The internal treatment is uncomplicated, safe and useful. Its basis is cold water. Large amounts of cold water are given at regular intervals. The food is milk and eggs. Stimulants and drugs are injurious, without exception.

Rheumatic Nature of Chorea.

Before the Eleventh International Medical Congress of Rome Sir Dyce Duckworth read a paper with the above title, a summary of which is here presented:

Chorea is not only related to rheumatism, but is itself a variety and a manifestation of this disease.

It is a form of cerebral rheumatism, representing one of the many extra-articular varieties of this disease.

Lesions may be found in the heart and in the brain, and, as far as we can say to-day, the cortical region is the part involved.

It is impossible to distinguish, during life or after death, any difference between the endocarditis due to rheumatism and that which is supposed to be due to chorea.

Shock, mental overwork or physical emotion are the causes ordinarily producing chorea, but these can give rise to the disease only in children who have inherited the rheumatic habit.

The symptoms of chorea point to the action of certain systemic poisons, and as these have been shown to be the efficient cause of rheumatism in about 80 per cent. of all cases, so we ought to conclude that they are the efficient cause of all cases of chorea, or that at most in a small percentage the disease results from the action of some other toxic substance having a remarkable affinity to the rheumatic poison.

As the manifestations of rheumatism are now clinically recognized in parts of the body other than the joints, so chorea may be considered as a variety of rheumatism specially affecting the brain.—*Med. Age.*

ANATOMY.

Anatomy of Fallopian Tubes.

Mary Dixon Jones (*Amer. Jour. Obstet.*) has distinguished six layers of smooth muscular tissue in the human Fallopian tube. The two main layers are the circular and longitudinal. They interlace, and the circular layer, which is the thicker, is nearest the canal of the tube. The inner surface of the tube is made up of submucous myxofibrous connective tissue, supplied with a broader longitudinal and a narrow circular layer of muscle. The mucosa has numerous folds which ramify, and are the result of alternate contractions and extensions of the two muscular layers of the submucous tissue. Outside the longitudinal muscular fibers of the tube wall is a layer of arteries and veins arranged as in the corresponding vascular tissue in the wall of the uterus. Two oblique layers of muscular fiber are interposed between these vessels and the investing peritoneum. Dixon Jones can fine nothing on the mucous membrane of the Fallopian tubes of the human female, even by high powers of the microscope, that would justify the definition of glands.

OBSERVATIONS UPON THE CHARACTER AND MANAGEMENT OF TYPHOID FEVER.*

C. Z. WEBER, M.D., Norristown, Pa.

Reviewing the records of cases treated during a period of now almost twelve years of continuous practice in this community, I find that in the treatment of this malady I have obtained results sufficiently satisfactory to warrant me in presenting them briefly for your consideration.

Typhoid fever, now universally recognized as a germ disease, self-limited probably as to length of duration, highly infectious and slightly, if at all, contagious, presents features somewhat varied in character according to the geographical location in which it is found.

Upon reading numerous authors who have written voluminously upon this subject, the conviction is forced upon us that in this locality at least we do not encounter the disease in its most virulent, if in its more nearly typical, form. True, "walking cases" such as we occasionally meet with here are described also by these authors, and upon the other hand, we are careful to take cognizance of the cases in which serious brain symptoms accompany the early stages of the disease; but the grave course usually ascribed to the disease is found in only a comparatively small number of our cases. With reference to the milder class of cases, however, I firmly believe that wherever the disease prevails, cases occur more frequently than we are wont to admit of a type so mild and obscure that their true nature is not discovered by either family or physician, and positive evidence of its existence is only betrayed by late manifestations. As an illustration, we are all familiar with the tendency of mild cases of scarlet fever to run a course unobserved until albuminuria or dropsy manifest themselves to the medical attendant, whose suspicion is corroborated by an outbreak of other cases in the family or neighborhood by virtue of the active contagion that attaches to this affection.

For a clearer elucidation we may be pardoned for introducing the following classification of the varied forms of the disorder under treatment, given in the order of their frequency:

SUMMARY.

Uncomplicated* cases,	47
Abortive cases,	4
Walking cases,	4

*Read before the Montgomery County Medical Society, November 7, 1894.

*We use the term "uncomplicated" here synonymously with "typical," by which we refer to those in which the disease runs a comparatively typical course extending over a period approximating four weeks, at the expiration of which the evening temperature first registers at 98.4° F.

Cases	complicated	with	inflammatory rheumatism,	4
"	"	"	malaria,	4
"	"	"	neuralgia,	3
"	"	"	bronchitis,	2
"	"	"	hemorrhage,	2
"	"	"	intercurring pregnancy,	3
"	"	"	pneumonia,	1
"	"	"	general muscular cramps,	1
"	"	"	la grippe,	1
"	"	"	extra length of duration,	1
"	"	"	persistent subnormal temperature,	1

The management of these 78 cases resulted in 75 recoveries and 3 deaths. Of the deaths, 2 occurred in the class of "walking cases." Death No. 1 occurred July 6, 1886; presented the following history: Male, aged twenty-two years, nativity a Swede, occupation glass-blower, married. First saw him at my office June 29, 1886. He consulted me for something to cure "malaria," as he termed it, his complaint being that he had been obtaining office treatment from several physicians for the past two weeks, without apparent benefit to himself. He had been following his employment daily during this period. He complained of a general tired feeling, not improved by his nightly rest. He was ambitious to receive an unbroken month's pay, as this was the last before the annual shut-down in his line of business, and he stoutly maintained that he was not too ill to work. Obtaining a history of slight diarrhœa at times, occasional epistaxis, more or less headache, which he had been regarding as malaria, I took the temperature and was surprised to find it out of all proportion to both his subjective and objective symptoms. The thermometer registered 104.5° F. Succeeding, temporarily at least, in impressing him with the gravity of his condition, I advised him to go home and take to his bed, promising to visit him the following day. Under treatment and liquid diet for several days his condition improved so much that, becoming rebellious against confinement and restricted diet and at the same time distrustful, he insisted, after the lapse of four or five days, upon dressing and going downstairs; and in utter disregard of warning as to probable consequences, in order to prove that people are sometimes not as sick as the doctor makes them out, he threatened to join his family in a good square meal then in course of preparation, consisting of chicken pot-pie and seasonable vegetables. This occurred at my morning visit, and as I was growing tired in my efforts to convince a man that he was sick, after taking his temperature, which I found at 102.5°, I gave him formal notice of my immediate retirement from the case, and the patient was left to shoulder the responsibility of his venture.

Just after midnight of the same day I was recalled to the case, as he was reported suffering from intense pain in the abdomen, and it was feared he was in a critical condition. Upon reaching the bedside I found the patient in most agonizing pain; the body bathed in a profuse cold perspiration; a feeble rapid pulse, if a pulsation could be said to exist at all; a greatly distended abdomen; the countenance anxious and changed almost beyond recognition; in fact, every indication that a perforation of the bowel had taken place. He presented a sorry contrast, indeed, with the defiant, venturesome, though foolhardy man of a few hours before. He had partaken of the injudicious food, and under the circumstances the only thing to be looked for was the certain death which followed in a few hours. A post mortem was denied, but there could be no doubt as to the cause of death.

Fatal case No. 2 presented the following history: Young man; single; aged seventeen; apprenticed to the carpenter trade, which employment he was following daily. Having an annoying headache and feeling unusual fatigue from his daily work, he availed himself of office advice and treatment from two physicians for upward of a week. His objective symptoms, a lack of energy and depressed spirits, strangely associated with an inordinate appetite, very naturally aroused the anxiety of his parents, who summoned me to see him at the end of his day's work. He had just finished a hearty supper, such as is usually provided for a laborer who is accustomed to subsist upon cold dinners. He informed me that he was not feeling very sick, and in his opinion he only needed rest, as the weather had been warm and the work unusually hard for the past week. Upon questioning him pointedly I obtained a *suspicious* history, and was astonished to find his temperature to be 104° F. He was ordered to bed forthwith, the diet restricted and an antipyretic administered at regular intervals. A light dose of castor oil was ordered for

the following morning, to be taken fasting, with view of correcting a slightly painful diarrhœa and also ridding the alimentary tract of any offending material most likely to have been injested.

A slight reduction in the temperature followed. The antipyretic in small doses was continued tentatively until a diagnosis could be reached. All was now so well that upon my visit August 17th, having been first called August 14th, there was a strong probability that the typhoid fever view was erroneous. Upon the following day, however, I was hastily summoned to the house. Upon making an examination I found the patient in a condition of collapse, having complained an hour previously of a severe and sudden pain in the neighborhood of the umbilicus. A hypodermic injection of morphia with atropia was administered, and upon returning to the bedside about one hour later there was revealed a greatly distended abdomen, and while the character of the circulation was slightly improved it proved to be but temporary, his condition growing rapidly worse, death resulting early the following day. A post mortem disclosed a perforation of the bowel, as was suspected from the symptoms exhibited.

Death No. 3 occurred in a female, aged forty-six, on the fourteenth day of what had been a case of moderate severity, as temperature had not registered above 103.5° even during the first five days of the attack. In this case it was not found necessary to push the antipyretic treatment after the first few days. The immediate cause of death here was paralysis of the heart induced by exhausted vitality, the combined result of grief, the climacteric period and typhoid fever.

We would divide the treatment of typhoid fever into two periods, viz.: that conducted while arriving at a diagnosis and that employed in the treatment of the disease proper.

As a means of establishing a diagnosis a reliable thermometer is of incalculable value. Whether consulted at office or visiting at patient's home, the practice of taking the temperature is absolutely indispensable. In this age of criticism I would greatly prefer to be ridiculed for the excessive use of the thermometer than be charged with any one of the sins of omission that might be attributed to neglect. If a temperature of 102° or thereabout is found to be present, accompanied with symptoms of general malaise, loss of appetite and evidence of greatly impaired nutrition; with a history covering a period of from several days to as many weeks of a general broken-down state of health; with irregular periods of diarrhœa and constipation; inability to sleep at night and an inclination to sleep in daytime; more or less headache; if not a decided chill, then chilliness; a coated tongue and its concomitant a bad taste; bad state of the mucous secretion, especially in the nasal region where rupture of the capillaries (epistaxis) takes place, etc.—with this array of symptoms I am at least suspicious of typhoid fever. If the bowels have not been freely moved some time during the preceding twenty-four hours, one grain of calomel is administered, followed in from two to four hours by a saline, as for example one-half to a teaspoonful of Epsom salts or a Seidlitz powder. With a view to eliminate the possibility of the presence of intermittent fever, two hours after the administration of the saline quinia is commenced with and continued in from two to five grain doses until twenty grains in all are taken. This should be managed so that twenty grains are administered in as many hours from the time the temperature was taken. If at the next visit the bowels are found to have acted with inordinate frequency, a point in diagnosis in support of your suspicion is established. Further, if the temperature is found to be higher by a degree or more than twenty-four hours previously, the suspicion may be presumed to be still further founded upon fact.

Notwithstanding the increase of fever, the treatment so far may have produced such an amelioration in the subjective symptoms that the patient feels that he is ready to return to his employment. The temperature may now be found to approximate 102.5° perhaps, and we find ourselves confronted with "a fever." So directing the patient to bed we commence with an antipyretic in doses sufficient to control the temperature, while we wait for several days to further corroborate our suspicioned diagnosis by the appearance of "rose-colored spots" or other unmistakable signs of typhoid fever. In the mean time our antipyretic treatment is being supplemented by having the patient's body

sponged with tepid water as frequently as the surface becomes hot and dry, and during this interval also a grain of calomel, followed as often with a saline laxative, is given on alternate days with a view of clearing the alimentary tract so far as practicable of its probable obnoxious contents.

The antipyretic we have been employing thus far is salicylate of soda, a remedy without which, in the light of our observation and experience, we would feel greatly handicapped in assuming the responsibility of the management of a case of typhoid fever.

The physiological action of this remedy being both *antipyretic* and *antiseptic,* we have at once an implement of warfare commensurate in a large degree with the destructive power of the enemy attacked.

Should you be deceived in your diagnosis, the treatment thus far pursued will have done no manner of harm to the patient, and nine times in ten, should you not be dealing with a case of typhoid, you will be surprised to find the patient's temperature gradually approach the normal and his convalescence brought about. It is but fair to state that even in what subsequently prove to be genuine cases of typhoid fever, about the end of the first week the temperature will sometimes be found to be at or even below the normal if taken in the early morning.

Should such a contingency occasion doubt as to the correctness of the diagnosis, it could be quickly dispelled by withholding the antipyretic until a later visit.

Should it be proven that you have been coping with genuine typhoid during this time, you have been passing through the most troublesome part in the management of the case. The anxious sufferer, in a greater or less confused state of mind, has been endeavoring to keep track of his business, but this interest in his personal affairs has gradually lapsed into an entire indifference with reference to his surroundings, while the family, prompted to action by their over-zealous relatives and neighbors, have been a unit as to your seeming stupidity in not being able to make a diagnosis upon your very first visit. And should you be so unfortunate as to be a recent graduate, while you may not have been openly asked to make an "unconditional surrender" of the case by the time the first crop of rose-colored spots exhibit themselves upon the surface of the patient's epigastrium, you have felt nevertheless that your destiny in the case has been wavering in the balance of the family's dissatisfaction.

After much tribulation, so to speak, the diagnosis of typhoid fever is fully established. Some responsible person in the family or the sufferer's nearest friend is now informed of the opinion reached, whereupon we take pains to explain that in the course of this disease there are two dangerous symptoms likely to be encountered, viz., hemorrhage and perforation of the bowel, and we at once enlist the hearty coöperation of the family or nurse in the supply of nourishment safely suitable for the patient. Up to this point the patient has been supplied with a moderate allowance of water, but has taken very little in the way of diet.

For a period of several weeks, determined of course by the length of time the disease has already run, and as carefully persisted in for two weeks after convalescence is begun, the diet should consist solely of milk and meat broths with an occasional addition of light farinaceous desserts, specially cooked soft-boiled eggs, allowing plenty of pure, cold, but not iced water.

At this stage dilute hydrochloric acid is added to the medicinal treatment. So with salicylate of soda and hydrochloric acid on the one hand and with milk and meat broths upon the other, we proceed to fortify the patient against the ravages of the disease at the same time we lift up the barriers of vital force which enable him eventually to overthrow it.

In the administration of salicylate of soda, from eight to fifteen grains will usually be found sufficient to hold the temperature within safe limits. I am in the habit of employing the following formula:

Sodæ salicylate.....	℥ ss
Elix. potass. brom.....	āā q. s. ad. ℥ij
Syr. sarsaparilla comp..	

M. Sig.: One-half to a teaspoonful every two to four hours.

The conjoined use of potassium bromide, five grains to the dram of the mixture, overcomes to some extent the slight ringing in the ears occasioned by the salicylate, besides exerting a favorable therapeutic effect upon the over-distended cerebral vessels.

I have always found it desirable to fix

the administration of the fever mixture at certain hours. Thus it may be given at the hours of 1, 5 and 9 A.M. and at 1, 5 and 9 P.M. If a thermometer be left with the nurse, the size of the dose to be given may be determined by taking the temperature at these stated intervals. At the discretion of the nurse also the doses due at 11 P.M. and 3 A.M. may be omitted as the medical attendant may advise. If the fever is running a mild course a half-teaspoonful of the mixture at the intervals stated will prove sufficient. A temperature of 102° to 102.5° F. is the limit above which it should not be permitted to run without administering proportionately increased doses of the antipyretic, supplemented of course with tepid-water sponging, which is found grateful to the patient's comfort.

The allowance of milk the patient is to receive should be given at least a half-hour before the antipyretic mixture, which enables both stomach and system to prepare for the coming dose. If a mild case is being dealt with salicylate may only be found necessary for its antiseptic effect, in which case it could be used every other time it would otherwise be employed; for instance, at 5 A.M. and the hours of 1 and 9 P.M. Assuming the hours for the administration of the salicylate to be fixed as above, the intervening even hours may be very systematically used for the administration of the hydrochloric acid and broths. They would therefore come at the hours of 3, 7 and 11 A.M and at 3, 7 and 11 P.M. I usually employ about from ten to twenty minims of the dilute hydrochloric acid in a wineglass or more of water immediately after the injestion of a cup of properly prepared broth, such as of beef, lamb, mutton or chicken, as the judgment of the nurse or physician may dictate. There can be no objection to the addition of a small portion of rice or barley to the broth if desired.

At the termination of the febrile stage and during the period of two weeks which should elapse before solid food could with propriety be allowed, semi-solids, such as baked potato with salt and butter, broiled, raw or stewed oysters with the eye discarded, stale bread or stale toasted bread without the crust and moistened with milk. Stale bread may also be allowed served with the milk dressing from fried ham or frizzled salt or fresh beef, the juice from under-done roast beef or broiled steak, any of which will be greatly relished by the patient, who is now beginning to call your attention to the savory odors ascending from the family cook stove.

Arriving now at the end of the third or fourth week, the patient is ready to be assisted to a sitting position, if not to an easy-chair, when an uninterrupted convalescence is anxiously hoped for.

Additional treatment found necessary in the management of typhoid fever will obviously be symptomatic.

For restlessness three to five grains of Dover's powder will not only produce sleep, but tranquilize both mind and body as well. If diarrhœa is a feature of the case, this same remedy may be given in the same doses after each excessive movement of the bowels. Should there be troublesome delirium, from ten to thirty grains of potassium bromide will have a happy sedative effect.

Should constipation characterize the case—and I find this to be a feature in about one third of the cases—the only safe agents to employ are castor oil in about one-dram doses or a carefully administered enema.

In the cases in which hemorrhage occurred morphia was given at once hypodermatically, and this followed at intervals of from two to three hours with from five to ten drops of deodorized tincture of opium until the period of danger was passed.

Of the three females whose cases were complicated with the pregnant state, two carried the fœtus to full term. The third aborted one month after convalescence was established. Quickening should have taken place during the progress of the fever, but as it did not manifest itself the death of the fœtus was suspected, which suspicion was in due time verified.

When typhoid fever was found complicated with other affections, such as rheumatism, bronchitis, intermittent fever, neuralgia, pneumonia, etc., these intercurrent maladies were combated with a line of treatment indicated for each when separately met with, modified as to agents employed and intervals of administration so as not to interfere or be incompatible with the treatment being pursued for the fever in hand.

As typhoid fever is known to be a highly infectious disease, the medical at-

tendant is not performing his whole duty to the family of the patient nor to the community without having made a thorough inspection of the premises and notably the water and milk supply of the family. While this may be too late to be of advantage to the patient, the health of the family or community may be in constant peril from the source from which the case in charge originated.

Ordinary fresh burned lime as obtained from the kiln for building or other purposes, properly prepared. is a germicide of recognized power, and it also has the advantage of being inexpensive and therefore within the ready command of even the humblest home. This should be kept in two forms: the one is obtained by treating the lime with hot water until reduced to a proper consistence; the other with just sufficient water to cause the lime to crumble into an impalpable powder. To destroy as far as practicable the poison germs in the dejections, the nurse is instructed to keep a bed-pan or a vessel charged with about a quart of the lime of about the consistence of thick cream in readiness at all times to receive the stools. This should be thoroughly incorporated with the lime by stirring before it is buried in the earth, which should be at a place safely remote from all sources of water supply for drinking purposes. The closet, if a well and used by the victim of the disease prior to his treatment, should be sprinkled and dusted with a liberal supply of the freshly slaked dry lime, and this process repeated at regular intervals until it can be emptied and the empty well disinfected in like manner.

OVARIAN CYST.*

E. E. MONTGOMERY, M.D., PHILADELPHIA.

In my clinical work before you during this year, it shall be my aim not so much to attract your attention by the operations that are done as to make a true exhibit of the work that should be done in the class of cases which will be met with in the gynecological field. My aim shall be to teach you to save rather than to destroy, to restore to the normal condition rather than to sacrifice. The tendency of the present time is toward conservation rather than mutilation.

The first patient I show you is a woman sixty-one years of age; her father died at ninety-three, her mother of some lingering disease, and her maternal grandmother died of cancer of the face. She is married, has had eight children and one miscarriage. All her children are in good health. Her menstruation began at fifteen, the menopause occurred at fifty-one, and the present trouble followed. She suffers from lumbar pain, particularly in the right side. This has been much aggravated during the last six months, when the pain has been almost constant. From the lumbar region it has extended over the abdomen. She has had constipation during her entire life; has gone at times days and even weeks without defecation. She suffers from a leucorrhœa which is increased of late; micturition is very frequent, sometimes passing urine as often as one hundred times in twenty-four hours. This urine contains blood and pus; the specific gravity is 1018; color light yellow; no albumen is present, but it contains blood-casts. She is somewhat emaciated, has lost considerable flesh and is weak and debilitated. As we look at her abdomen we notice that it is not regular and symmetrical, and there is that relaxation of the abdominal walls which we would expect present in a woman who has given birth to eight children. It is not surprising, consequently, to find the abdomen flattened out and somewhat irregular, even though there was nothing abnormal in the abdominal cavity. You will notice, however, it projects more especially on the right side. This projection is limited to the spaces above and below the umbilicus and is more prominent on the right side, so we do not have a symmetrical distention. If this distention were mere obesity we would expect to

* Clinical lecture delivered at the Jefferson Hospital.

find it characterized the abdomen alone and there would be more or less prominence, which would be situated at the lower part of the abdomen and would likely be symmetrical—that is, it would be the same on either side. In this patient, however, as she lies on her back, the distention of the abdomen is not symmetrical but is very marked to the right.

In any disease of the abdomen we take into consideration the fact that there are in the abdominal cavity certain viscera. Any of these viscera may give rise to growths which produce very characteristic symptoms. In order, then, to arrive at a definite diagnosis of the character of any growth and the organs by which it is affected, we mark out the abdominal surface by arbitrary lines into a number of spaces; thus we draw a line across the level of the eighth rib, another at the level of the highest point of the crest of the ilia. These lines divide the abdomen into three spaces; these are subdivided by a perpendicular line bisecting Poupart's ligament, which consequently divides the abdomen into nine spaces, from above and to the right and left hypochondriac and the hypogastric, and the right and left lumbar and umbilical, the right and left iliac and the hypogastric regions. In each of these divisions of the abdomen we recognize there are situated portions of different viscera. On the right above we have the upper part of the liver, the right kidney, the ascending colon, and on the left the spleen, the left kidney, the descending colon. In the epigastric region we have the stomach, the left lobe of the liver and the gall-bladder. We also have the colon, the small intestine, and in the lower portion of the abdomen in the hypogastric region we have the uterus and bladder, and on either side the ovaries and posteriorly the rectum. In the right lumbar region distentions may arise as a result of inflammation about the appendix or cæcum. In addition to the conditions named, we may have enlargement of the abdomen from the presence of growths in the mesentery and omentum or from retroperitoneal tumors. If a patient, then, presents herself suffering from an abdominal tumor, we endeavor by inspection and palpation to determine the portion of the abdomen in which it is directly situated. Having determined this, we take into consideration the viscera of that region and endeavor by a process of elimination to satisfy ourselves as to the particular portion of viscus involved. This tumor is situated altogether to the right of the abdomen; it consequently may be due either to enlargement of the liver, to a condition of the kidney, to malignant disease possibly of the ascending colon, a growth situated more particularly in the lower part of the abdomen, which may be determined also by vaginal examination, may arise from the ovaries or uterus or growths involving the intestine in that region.

The methods by which we examine a patient may be divided into inspection, palpation, percussion, auscultation and exploratory incision. By inspection we recognize any irregularity in the abdomen, the part in which it is situated, discolorations of the cervix, cicatrices or striæ. These are quite marked in this patient, indicating the abdomen has undergone such distention as to cause rupture of its pigmentary layer. These striæ are frequent in pregnancy. Rarely does a woman attain to the full term without more or less of such phenomena present. While this is considered as one of the signs of pregnancy, it should be kept in mind that it is not a result of pregnancy alone, but of any condition which causes sufficient distention of the surface to bring about such a change in the skin. It may result from ovarian or fibroid tumors, from a distention from ascites or obesity. The discolorations of the skin should be noted. These are more marked in the brunette, less so in the blonde. Pigmentation in the skin in some cases is very extensive. These discolorations also are not confined to pregnancy. In a woman who has been pregnant we frequently find a dark line known as the linea nigra, running from the umbilicus to the symphysis, in some cases even extending to the xiphoid appendix. We also find more or less discolorations of the skin on either side. These discolorations take place in other distentions of the abdomen, as ovarian disease and uterine growths, and are in particular characteristic of some forms of amenorrhœa. Indeed, it has been asserted that the change in pigmentation is due not so much to the fact that the woman is pregnant, but to the arrest of menstruation; that there is an elimination of material through menstruation

which would otherwise be deposited in the skin. There are other discolorations which result from inflammatory conditions produced by various counter-irritant applications. These serve to throw light on the previous history of the patient. For the inspection the patient is placed upon a table or bed, the abdomen is bared and a sheet placed over the lower extremities, making it hug closely the lower part of the abdomen.

While we conduct the inspection we may proceed with palpation. This is performed by placing the hands over the abdomen, sometimes in grasping the entire abdomen, at others bringing the hands closely together from side to side over the distended parts, and in this way securing a definite idea of the size, consistency, regularity and mobility of the growth. In so doing we determine whether it is a solid or a fluid growth. By solid we mean one which is more or less made up of solid material. A cystic tumor is one which contains within a sac more or less fluid.

As the hand is placed over the abdomen in this patient, I notice on the left quite a considerable projection. It gives rise to fluctuation, or sensation of elasticity, which indicates fluid contents. At other points in this tumor there is a sensation not so distinctly determined which is more resistant, although a greater part of it would indicate that we had to deal with a cyst rather than with a solid body. Placing the hand over the abdomen and tapping on the opposite side, a distinct wave of fluctuation can be distinguished. This is particularly marked if the fluid is free in the abdominal cavity. It is marked also if the fluid is contained within a single cyst, but if you have one in which there are a number of divisions, the partitions will interfere with the fluctuation wave, rendering it less distinct, and where the cavities are small may make it indistinguishable. The wave here is distinct and extends over the side on which percussion is made. The symptom of fluctuation is one which should be carefully studied in every case, for by it we are enabled to determine whether the fluid is contained in a single sac or is free in the cavity.

By palpation I am led to assert that this growth contains fluid; that it is not a single sac, but composed of a number of sacs; consequently fluctuation does not present a long wave. In such cases there is a possibility of error. We may have in a fibroid tumor, as a result of interference with the circulation, the tumor become filled with fluid; in other words, it is œdematous. In such cases I have been in doubt whether we had not, instead of a fibroid tumor, a fibro-cystic tumor. I remember some years ago, in doing an operation upon a patient whom I had examined some three weeks before and had satisfied myself that she had a fibroid tumor, the pedicle was somewhat long and the tumor readily moved about. Three weeks after the first examination, when I came to operate upon her, the tumor had greatly increased in size, the growth had apparently been rapid, and there was a distinct sensation of fluctuation and elasticity, greater than we would find in the growth before us. If I had not examined the patient previously I would have been in doubt as to whether it was a cystic tumor or a fibroid. The operation was done, the tumor removed, and a distinguished surgeon and pathologist, taking up the mass, said it was a fibro-cystic tumor. With a knife he cut through it and did not find a single cyst. It was a fibroid whose circulation had been interfered with and the growth had become œdematous. The fibrous tissue was so separated by the fluid that it had given rise to the distinct sensation of fluctuation to such a degree as to lead this experienced gentleman to believe it was a cyst.

In the case before us the irregularity of the growth, with its sensation, renders it impossible that it can be due to an œdematous solid tumor, consequently a tumor containing a number of small cysts. Solid tumors in a woman of this age are rare. Fibroid tumors have their greatest activity prior to the menopause. Subsequent to the climacteric a solid growth which has increased rapidly in size is more than likely malignant. That this is not a malignant growth is rendered probable by the fact that it has been in existence for ten years. It began shortly after the menopause, has increased in size, although the patient within the last year has felt more discomfort and distress than prior to that period.

There is but little to be learned by either auscultation or percussion. Percussion enables us to outline the relation of the intestine to the tumor, and as I pass to the

left we recognize the intestinal resonance. In other words, this tumor, having begun on the right side of the abdomen and increased in size, has pushed the intestine to the left and upward. When I examined this patient a few days ago I was in doubt as to the character of the growth and the organ from which it originated. Of course, in considering the growth itself, as it is more upon the right side we have thought of the possibility of it having originated from the liver, kidney, ovary, or as a growth from the uterus.

That this tumor is not one of the liver we are inclined to believe from the fact that it is situated low down in the pelvis; there is not the distention of the upper part of the abdomen; we are able to pass the finger between the tumor and the ribs and to determine that it does not extend beneath the ribs. Further than that, as we palpate we can notice a line of resonance between the tumor and the liver, so excluding the liver.

We next consider the possibility of its having originated in the kidney. The tumor is situated well upon the right side, more marked on the right than the left; it is very much in the situation we would expect a tumor which had developed from the kidney. A tumor in the kidney attaining considerable size will project beyond the median line. This patient gives a history of frequent micturition, of having evacuated pus and blood with the urine; a history of deficient amount of urine, not more than eighteen ounces in twenty-four hours. All these symptoms would indicate the possibility of this being a diseased condition which may have originated in the kidney. When we consider the growth of the tumor, its situation, that it extends over toward the left side, fills up the space extending transversely across the abdomen, much wider transversely than vertically, that there is a slight sensation of fluctuation and the tumor is irregular, it becomes improbable that it has originated in the kidney; as a diseased condition of the kidney to give rise to a tumor of this size must be either inflammatory or malignant. Inflammatory disease may arise as a result of calculi in the renal pelvis; the presence of calculi may produce distention from the subsequent irritation, infection and suppuration. It is not unusual for such tumors to attain large size. I operated only a few days ago upon a tumor as prominent as this on the left side of the patient which did not project as far beyond the median line as this does. In that patient we found a quart of pus. It had originated from a calculus in the pelvis. But the history in this patient is not that of an inflammatory condition. We find no indication from the temperature record of any marked deviation from the normal. I am not, then, inclined to believe, from the appearance of this tumor and the length of time it has been in existence, that it is a distention of the kidney as a result of suppuration. In this consideration I believe the decreased amount of urine and the deposit of blood and pus may be due to pressure upon the ureters, possibly also upon the kidney, but particularly upon the bladder. The length of time the patient has been carrying it, ten years, is too great, it seems to me, for the growth to be due to the presence of pus alone.

Eliminating the probability of this growth being one of the kidney, we question the possibility of it being disease of the ascending colon. She gives no history of obstruction, while she is suffering from constipation. The absence of obstruction does not justify such a diagnosis. The tumor has been increasing in size. We are enabled to eliminate the probability of it being malignant disease of the intestine, while it is difficult to determine externally what we may find within the abdomen.

We are confined, then, to the probability of its being a growth of the uterus, of the ovary, or a retroperitoneal tumor. In retroperitoneal tumors we would expect to find, as it increases in size, the colon would be pushed in front of it, possibly over it. In this case the colon is situated to one side and not over the growth, consequently this tumor is within the peritoneum. I operated a little over a year ago upon a patient who had had a tumor for nine years in which there was marked distention of the abdomen and a distinct sensation of fluctuation. Although there was a line of readily recognized resonance running over its side, I had no hesitancy in believing it was an ovarian growth. The abdomen was opened, when it was found the tumor was situated behind the peritoneum. The peritoneum was opened, a trocar plunged into the tumor and the latter subsequently drawn out, leaving the

entire left side of the abdomen denuded. In this space the kidney could be seen distended and sacculated. So distended was it that it resembled a cyst, and after inspection it was decided to remove it. The fact that the line of resonance extended over the side of this tumor in the situation of the colon should have led me to suspect the possibility of it being other than an ovarian tumor. It is not impossible that in some forms of cysts of the ovary the situation may be such as to simulate very closely a retroperitoneal cyst, but such cases are rare.

As I make a vaginal examination of this patient I find the uterus is pushed down and rests beneath the tumor; that it can be easily moved over its surface, so that we are driven to the conclusion that this is a tumor of the right ovary, of a cystic character, containing a number of small cysts; that its contents are probably thick and viscid, and there are without doubt a number of adhesions. Before proceeding to consider operation in this case we will have the urine tested, and if it is eliminated in proper quantity we will proceed to prepare her for operation.

THE VARIOUS OPERATIONS FOR THE RELIEF OF CHRONIC AND SCLEROSED MIDDLE EAR CATARRHAL INFLAMMATIONS, AND WHEN SUCH SHOULD BE PERFORMED.

LAURENCE TURNBULL,* M.D., PH.G., PHILADELPHIA.

A large number of individuals are susceptible to sudden changes of temperature, exposure to draughts or currents of air striking any part of the body, but especially the back of the neck, feet or an uncovered part. They soon feel that they have taken what is termed a "cold," the first symptom of which is sneezing. This is followed by a watery discharge from the nostrils and by swelling of the membrane covering the turbinated bones. If this condition is not promptly treated by a solution of cocaine to the nostrils, with five grains of Dover's powder at night, so as to keep the skin warm and moist, the inflammation progresses and the discharge becomes mucous, yellow or yellowish-green, from a mixture of the blood corpuscles from the surface of the membrane which has become abraded. This condition should be promptly treated by mild antiseptics, alkaline washes, the use of Politzer's air douche and large doses of quinine.

The patient usually recovers rapidly from the acute symptoms, but if neglected there may be as complications not simply a stuffy feeling with itching in the ears, but tinnitus aurium and perforation of the membrana tympani, known in common parlance as a "running ear," or otorrhœa. This in scientific language is termed otitis media purulentia. If the head or brain become involved and there is no perforation, it is then necessary to perforate the drum membrane to relieve the patient. The dry treatment with boracic acid is then employed, keeping the Eustachian tubes free.

Instead of this acute course there is what is termed the catarrhal adhesive process, causing thickening of the membrana tympani with a great increase in deafness from constant attacks. Then occur alterations with contractions, calcifications, ossifications of the bones of the middle ear and obstructions of the Eustachian tubes, when it is termed sclerosed. In some persons the deafness increases slowly for months or years perhaps, while in others it is very rapid from effusion of blood, serum or lymph involving the stapes, oval window (fenestra ovalis), labyrinth or the vicinity of the auditory nerve. The bones of the ear become anchylosed or fixed by bands of lymph, or they are found to be ulcerated and more or less dried and destroyed, acting as foreign bodies producing distressing noises. These processes with deafness are increased from hereditary predisposition, also from anæmia, scrofula, tuberculosis or constitutional syphilis.

The diagnosis from the first class is not

* Aural Surgeon to the Jefferson Medical College Hospital, etc.

difficult by careful consideration of the appearance of the membrana tympani, which is sunken from obstruction of the Eustachian tubes, often contains chalky deposits or shows practical atrophy. The test must be made by the watch and tuning-fork; also by the tests of Rinne and Weber. The use of the exhauster of Siegel and Delstanche is important, as by this method may be determined where are the adhesive portions of the membrane.

The prognosis is almost always unfavorable. Even after long treatment by injection of medicated air into the middle ear, by the use of vapors or solutions, by rarefaction and stimulation, a relapse is apt to occur if the treatment is not long enough continued.

It will be well before finishing this part of our subject to dwell for a few moments on the tests before mentioned, those of Rinne and of Weber. The first was brought forward in 1855. Rinne stated that in those cases in which the tuning-fork is heard longer through the cranial bones than before the ear a disturbance of the sound-conducting apparatus exists. This is known as "negative Rinne." Where, on the contrary, the tuning-fork is perceived longer before the ear than through the cranial bones ("positive Rinne"), it indicates, according to Rinne, a disease of the auditory nerve apparatus.

In Weber's test it was found that if sound conduction to the labyrinth was hindered by pathological changes in the external meatus or the middle ear, a vibrating tuning-fork placed on the middle line of the skull will be heard most distinctly in that ear where the pathological change occurs. In using the test the handle of the tuning-fork is set on the medial line of the skull, or on the median line of the upper lip against the incisor teeth, or on the median line of the lower jaw.

COMMUNICATIONS.

"SOME SURGICAL SINS"—REMARKS ON A PAPER CRITICISING THE PROFESSION.*

M. PRICE, M.D., PHILADELPHIA.

I wish to call attention to a paper which I think has grossly misrepresented the profession.

On the first pages of the *Journal of the American Medical Association* for June, 1894, is a short paper headed "Some Surgical Sins," the writer of which must speak from personal knowledge of a condition of things that every true lover of surgery who works for the best interests of his patient and the advancement of the profession would indignantly repudiate.

Why, then, this savage attack on the surgeons of the world? Are they any less honest or truthful than the writer of this paper which has been given such a prominent position in the organ of our national medical organization, a periodical which is supposed to represent the profession of the country and is the guide to many of the medical profession? I think these criticisms should be repelled.

Let us examine some of the statements of this champion of surgical honor and truthfulness. He says: "A very significant fact in the surgical literature of recent months has been the evidence of reaction against an over-hasty adoption of operative methods of treatment." I deny that the surgeons of this country ever recommended surgical treatment until they were convinced that operation was the only proper treatment. There is no evidence anywhere in surgical writings and reports that I can find of any change in the methods of competent surgeons in this or any other country, substituting medical treatment for surgical in any condition which they have selected for operative interfence. Those who are influenced

*Read before the Philadelphia County Medical Society, December 26, 1894.

by such statements may be guilty of operations for imaginary surgical conditions, something that no *surgeon* would be ever guilty of.

"The low death-rate of the new surgery made such a contrast with the mortality recorded in accepted text-books that the men who believe the new gospel, naturally the young, were enchanted by the safety with which they could operate for conditions that older and more cautious surgeons hesitated to so treat. Many of us have stood appalled at the temerity and astonished at the pathology of these operative members of the profession."

"The low death-rate of the new surgery." How strange that it should be the young who so quickly appreciate the wonderful improvements in surgical sciences and apply them to the wants of the suffering; and how much greater would be the surprise to know that any, no matter how they may have deteriorated in surgery, could go back and for one moment think of comparing success in abdominal surgery in saving lives in conditions tenfold more dangerous than those laid down in the so-called "accepted text-books" of the profession. Is it possible for any one who lays claim to a surgical education, who has devoted any time or consideration to the technique of abdominal surgery, to conceive of such mortality as laid down by the so-called "accepted text-books?" Would they not in turn stand appalled at the horrible record? From 25 per cent. to 75 per cent. of deaths in the so-called "accepted text-books" of abdominal surgery! The time may come when the older surgeons—those who have devoted their entire lives to not the one branch of surgery, but to the whole seven branches of medicine as laid down by our schools, and have attempted to be able and efficient teachers and operators in every specialty now recognized by the surgical world; those who have operated for cataract, for fissure of the bowel, for carotid aneurism, for ingrown toe-nail, for hysterectomy and for every operation in the known catalogue of surgical diseases, and claimed to be proficient in all alike (and no doubt they were)—will recognize the fact that the eye surgeon should have special preparation and opportunity, and should devote himself for many years to this specialty alone, before he is competent to perform operation for the relief of disease requiring operative interference, and that in the same way is special work, devotion and consecration needed in the other branches. I heartily indorse the idea that a man should have a general knowledge of medicine and surgery; that if he selects a specialty, it should be in the direction that most pleases and interests him. From these facts alone he will do better work, be a more competent operator, take more interest in his patients, and give more attention and care to every detail to acquire perfection in his specialty.

"Look at the dozens of operations by me this year without a death," says the operator. His less enthusiastic neighbor thinks of the proverbial kinds of falsehoods, "lies, damned lies and statistics."

When we remember that the writer of this short description of the surgical enthusiast refers to those of the profession who claim more for their reported work than did the writers of the so-called "accepted text-books" of surgery, this statement is truly appalling. So far as I know the entire profession repudiates the old statistics of the so-called "accepted text-books" of surgery and claims a much lower death-rate than do they, and I do not think that the profession at large doubts that the great majority of operators are honest and truthful in the report of their work. I believe with Dr. Roberts, that no man in our profession should be guilty of reporting his cases save with the most absolute accuracy. I believe the medical profession to be many degrees less addicted to untruthful and dishonest misrepresentations than any other calling which men accept as their life-work. I think with Dr. Roberts, that "liar" should be properly stamped on the man misreporting his work, but one should not brand the whole profession with falsehood because some happen to devote their lives, their energy and their money to one of the seven branches of medicine, in order that they may the better understand and care for the patients intrusted to their care. Mr. Tait has done over one hundred operations without a death—the most desperate along with the most easy; Mr. Keith reports dozens of the most terribly neglected cases of hysterectomy without a death; Joseph Price has done more than a hundred operations as they come in abdominal surgery without a death; and

there are many other operators in this country, with many dozens of operations to their credit, without a death to tarnish the record. Why, then, this charge of falsehood? Can Dr. Roberts give the name of a single surgeon of any reputation that this shameful charge will fit?

"Demanding unusually large fees for professional services is a surgical sin which the increasing number of skilled surgeons is happily correcting. To send a bill for a large amount simply because a patient is wealthy does not appear to be just, and to obtain the money because the patient is in fear of death and dare not employ a less experienced attendant, makes one think of the methods of the footpad, who demands your money or your life."

For skiled services in the arts and sciences, in medicine, surgery and the law, in painting and the ministry, it has been the rule the world over since the world began for the better class of all workers to be paid in proportion to skill. The painter demands, in proportion to his reputation and skill in the art of painting, many thousands more than his less skillful rival. The poor man pays $5 at the bazaar for the horse which will answer his purpose; the rich man, for one that will meet his requirements, pays $150,000 and thinks himself fortunate in his possession. For the surgeon to value his services to the rich and poor alike would be an injustice both to the profession and to the patient. Fortunately for the surgeon, the rich do not expect any such moderation. I have always found that the most grateful people I have had the pleasure to attend have been those from whom I have demanded very large fees and those from whom I demanded no fee at all. In abdominal surgery, the proportion of those who pay nothing to those who pay a fee is about as ten to one. No abdominal surgeon that I know of ever refuses to go to the relief of a patient demanding his services, and to go entirely irrespective of whether or not there will be a fee. When this is considered on the one hand, and on the other Dr. Roberts' charge that the surgeon uses methods in common with the footpad, demanding the money or the life of the patient, one cannot but feel that the imputation would be both offensive and disgraceful coming from a citizen who owed a bill to a surgeon, but from one of our own profession it is adding insult to injury.

"Due regard is not given by us to the influence of the nervous system upon the health. Many patients can be cured by medicine or psychic remedies of symptoms that would induce some surgeons to resort at once to mutilating operations. This statement does not apply alone to pelvic conditions, but to affections of joints, muscles and viscera."

If Dr. Roberts had indicated that want of consideration of nervous symptoms obtained in disease in general instead of in surgical conditions only, we might think the charge worthy of serious notice; but when it is said that the surgeon does not properly consider the nervous element I must beg to differ with him. The surgeon has no excuse for such a mistake, nor for accepting nervous symptoms as reason for any surgical operation. If the operator can find nothing but nervous phenomena—no pathological changes, no tumor nor deformity of parts to warrant interference—he has no cause for operating. The patient should be treated for the condition present and not one manufactured by the attendant to fit his notion of treatment.

The system of medical education in the United States, in laying so much stress on the complications and dangerous conditions to which all patients are exposed, leads the student when he leaves college to suppose that his very first case will be a Waterloo. He has been taught in some of our colleges so many dangerous complications in midwifery and has learned of so many frightful operations that in his estimation scarce one patient in a hundred can escape mutilation for her relief and delivery. This city alone yearly sends out a half thousand young men and women, so many of whom have been constantly listening to this dangerous side of medicine and surgery that we cannot wonder that so many operations are thought of, talked about and considered by the young attendant and that so many mistakes are made by him through overanxiety and misapplied interpretations of symptoms. Every year lessens the dangers to the patient in this direction and gives us a set of men in the community that we can depend on and believe them when they say that an operation is demanded, that there is no other way to

have perfectly healed, to be amply covered with a soft pliable integument permitting complete flexion and extension, pronation and supination; indeed, but that it is not quite so strong as the right arm, to have its functions entirely restored.

CASE II.—Anton D., thirty-three years of age, a fireman, was brought to the Episcopal Hospital October 25, 1892, with a railroad injury of his left foot. The extremity was so caught beneath the wheel that it had been completely flayed, but as none of the integument was lost it was brought together by sutures. Sloughing, however, occurred of the entire skin of the foot and ankle. December 4th a flap 2 inches wide was dissected from the sound limb, from the lower portion of the thigh to the lower third of the leg, a distance of 14 inches, its base being left attached at the lower part. Carrying the lower portion along the outer side of the foot from before backward, the flap was reflected upon itself around the heel, and its remaining portion carried forward on the inner side of the foot to the toes. It was retained in this position by sutures carried deeply enough through granulation tissue to take a firm hold, and through the reflected lower borders of the flap occupying the sole of the foot. With a Y-shaped splint ingeniously devised by Dr. Ferguson, which kept the injured foot in a state of absolute fixation to the calf of the leg on the sound side, the patient, with remarkable fortitude, kept his limbs in this constrained position for over three weeks (22 days), when the base of the flap was detached, the latter having become firmly adherent to the foot. Advantage was taken of this opportunity to gain a little more integument by dissecting the flap further down the leg instead of cutting it off level at the foot. The patient remained in the hospital 657 days, at the end of which period he walked without a cane and with a foot whose function was sufficiently restored to enable him to resume his laborious occupation of fireman on a vessel. The foot will be seen to be a very useful one, its plantar aspect being covered entirely by leg skin, as shown by the growth of hair upon it.

It will be observed in both of these cases that there is a singular freedom from the constriction of a tightly drawn peripheral cicatrix, œdema, impairment of function and other evidences of impeded return circulation. This factor alone places this method of closing large circumferential ulcers far in advance of the method by skin-grafting. Though the method of Thiersch and others, of allowing the flaps before severance at one or both extremities to become granulated, would have been applicable to the case operated upon six years ago, it is very doubtful if so long a flap as that transplanted in the other case would retain its vitality throughout its length, even if left attached at both ends.

PHLEGMON OF THE STOMACH.

WILLIAM VISSMAN, M.D., LOUISVILLE, KY.

A pathological specimen which will be of interest on account of the rarity of its like, if for no other reason, is a section of a stomach taken from the corpse of a laborer's wife.

The ante-mortem diagnosis was doubtful. However, carcinoma planum was supposed on account of age, fifty years, absence of hydrochloric acid in gastric juice, slight icterus, complete anorexia, vomiting, pain in epigastric region, no tumor, nourishment very bad. These conditions, with a history of a general indisposition for some time before entering the hospital, were the cause of the suspicion of the attending physicians.

The post mortem showed very slight thickening of endocardium, hypostasis in lungs slight, hyperplasia of spleen and cloudiness of liver and kidneys. Stomach was empty, walls about half-inch thick, and this thickness was continuous throughout the organ and extended a slight distance (about one inch) up the œsophagus.

The mucous membrane was thickened, pale and œdematous; the submucosa was

impregnated with a somewhat opaque, yellowish, gelatinous fluid which exuded on slight pressure. There was no other center of suppuration to be found in the body.

The microscopic examination of the stomach showed the greater part of the thickening of its walls to be due to the infiltration of the submucosa with pus. Not only is the submucosa infiltrated, but this infiltration follows the connective tissue throughout the entire walls. In other words, we have a phlegmon of the stomach enveloping the entire organ.

This condition can only be brought about in one of two ways, by metastasis or by direct infection, and when due to metastasis, as is very often the case in puerperal sepsis, is generally circumscribed (abscess of stomach). However, this is not necessarily the case.

Direct infection may take place from external injuries, as in Silcock's case after gastrostomy ("Trans. Lond. Path. Soc.," 1883), or it may take place from the inner surface, particularly after partaking of infected food. This mode will appear just a trifle implausible because the gastric fluid is supposed to be an excellent disinfectant, but the experiments of Falks ("Virchow's Archives," vol. xciii), which were proven a year later (*Deutsche Med. Wochenschrift*, 1884, No. 20) by Frank, show that the gastric fluid does not affect the power of proliferation of the tubercle bacillus. In the event that the patient lives until the phlegmon advances far enough to form abscesses, it is evident that the mucosa will be undermined to a great extent and very apt to become necrosed and cast off, as was reported by Laboulbene (*Bull. de l'Acad. de Med.*, 1876). This case was due to sulphuric acid, and two weeks after the ingestion a membrane 20 by 12 cm. was cast off.

These cases are sometimes diagnosed by finding large quantities of pus in the vomit.

Instead of forming a large abscess the mucous membrane may be perforated in a large number of places, but in either event it is very doubtful if any recovery has taken place.

As for symptoms and treatment, from the morbid anatomy they are obviously those of general sepsis. As to the frequency of these cases, I can add nothing to Rokitansky ("Lehrbach der Pat. Anat.," 1861), who says they are very rare. I have seen only this one among more than 10,000 post-mortem examinations; and Delafield and Prudden in 1892 report having seen only one case.

Painful Peritoneal Adhesions.

Nicaise (*Revue de Chirurgie*) states that the use of antiseptic methods and the consequent development of antiseptic surgery have made surgeons better acquainted with peritoneal adhesions and have led to their successful treatment by operation. These adhesions may give trouble by disturbing the function of implicated organs and by exciting pain. The pain varies in character and intensity in different cases. It may be caused by displacement of organs to which the adhesive bands are attached or by constriction of the intestinal canal. The pains in the latter condition are often very severe and of a similar nature to that of hepatic and renal colic.

The diagnosis of peritoneal adhesions is often very difficult. In some cases their existence can only be assumed by the process of exclusion, while in others their certainty can only be demonstrated by an exploratory operation. The author is of the opinion, however, that a diagnosis can be made in many cases by close inquiry concerning such details as previously occurring abdominal inflammation, the seat of pain, and the relation to the seat of any previous inflammation, the time when the pain comes on in regard to the taking of food.

As many peritoneal adhesions become longer and thinner and have a tendency to disappear, there should be no great hurry in having recourse to an operative procedure. When, however, they cause great pain, a laparotomy should be performed and the adhesions broken up. The cure that will thus be effected will be permanent and complete.

Chloroform Treatment of Phthisis.

In the *Jour. de Med. de Paris* Mr. Potter urges that by the inhalation of chloroform the bacillus of tuberculosis is destroyed *in situ*. It is not necessary to produce anesthesia, but short of this inhalations should be employed at brief intervals daily for a considerable period.

CORRESPONDENCE.

THE INJECTION TREATMENT OF HERNIA—REPLIES TO INQUIRIES.

EDITOR MEDICAL AND SURGICAL REPORTER:

Inquiries for further information regarding the injection treatment for hernia have become so frequent that I am compelled to answer through the columns of THE REPORTER.

First, as to the truss and its application. For scrotal hernia I prefer what is known as the "German scrotal truss." This is a soft padded truss easily adjusted and easy to the wearer. A perineal strap keeps it well in position. I have held old ruptures with this truss that could not be retained by any other form. Still, for an all-around truss the Hood pattern is probably the most satisfactory. Either of these may be obtained from the dealers. It is important in fitting a truss that it does not press upon the pubic bone. The pad should rest just above it. The spring of the truss should not press upon the body, but be bent so as to be perfectly comfortable, pressure being exerted only on the pad over the hernia and on the disk at the back; this pressure being only sufficient to keep the hernia well in. If such pressure produces excoriation, wash the parts with dilute alcohol, dry thoroughly and dust with stearate of zinc. Repeat as often as necessary.

Taxis.—The text-books give quite full instructions, to which the reader is referred. Taxis should not, however, be practiced for over fifteen minutes at a time with any patient. Let the patient rest for awhile and repeat; but it is better not to make too many attempts at reduction on the same day in obstinate cases. Prolonged taxis in any case is dangerous.

If strangulation has occurred and the bowel seems to be filled with gas, some operators recommend that it be punctured with a small hypodermic needle, detached from the syringe, and the gas allowed to escape. I see no objection to this procedure. Ice may be applied in strangulation, or a little ether poured over the parts. The ether by rapid evaporation produces intense cold which rapidly contracts the parts, frequently allowing of reduction.

The positive pole of a galvanic or a faradic battery has been successfully used with the negative at some other point. Contraction is caused and possible reduction.

Morphine, $\frac{1}{4}$ gr.; atropine, $\frac{1}{150}$ gr., and hyoscyamine amorphous, $\frac{1}{125}$ gr., combined in one hypodermic injection, has been used with prompt effect in strangulated hernia. Dosimetric granules of these alkaloids are a very convenient form for such administration. They are very soluble and a little dozen-vial case containing as many varieties, one hundred of each, is easily carried in the vest pocket.

Coughing Taxis.—Dr. Wherry, in the *Lancet*, says that he has frequently found that coughing on the part of the patient during taxis was a great aid in the reduction of hernia. He cites a case of femoral hernia, severely strangulated, in a middle-aged woman which he succeeded in reducing by gentle taxis continued for fifteen minutes, the patient coughing continuously. Two other physicians, aided by chloroform, had previously failed to reduce the hernia. This method is easy and safe and well worthy of trial before any other attempts are made.

"How shall I know when the patient is cured?" In an ordinary case one week after the sixth injection has been properly made the patient may stand, the truss be removed and the parts carefully examined to see if there be any signs of a protrusion. The patient may give a slight cough, which will give an impulse differing in character upon the two sides if there is still a hernia. With the finger these impulses may be readily differentiated after a little practice. If the hernia seems to be well, allow two weeks to pass, when another examination should be made. Of course the truss must be worn as usual, and finally not laid aside without the consent of the operator.

In one month after the last injection you will be able to determine whether further treatment is necessary. There

may be a weak point that needs reinforcing. Keep the patient under observation for at least six months, with monthly inspections, in order to prevent a relapse through carelessness on his part. He should not be allowed to put undue strain upon the parts until they are thoroughly healed.

The operation for femoral hernia is practically the same as for the inguinal variety: reduce the protrusion, follow up the canal with the trocar and canula needle, and proceed to obliterate it by producing the proper amount of adhesive inflammation.

The object aimed at is to close up the opening by which the bowel leaves the abdomen, whether this be femoral, inguinal or umbilical.

For these operations only a suitable trocar and canula needle and a proper fluid should be used. Safety and success depend absolutely upon those two requisites. The skill to use them is readily acquired.

The injection method has established a permanent position in the treatment of reducible hernia, and the percentage of cures is greater than by operative procedure if proper instruments and fluid be used. Progressive physicians all over the country are adopting it with good success.

Philadelphia.

VALVULAR HEART DISEASE, WITH PARTICULAR REFERENCE TO THE USE OF STRYCHNINE.

In the opinion of Dr. Meffler (*Med. Record*), medicines should be dispensed with in valvular diseases of the heart as long as compensation is complete and hypertrophy does not provoke any marked secondary symptoms. Absolute rest is, of course, of prime importance. There should be regular hours of rising and retiring. The daily exercise should stop short of producing fatigue. The mind should be cheerfully occupied. He advises simple nutrition, without overloading the stomach; hence frequent small meals, rather than heavy dinners; very little fat, sugar and succulent vegetables; let the patient partake of nitrogenous, albuminous food, and abstain from stimulating drinks.

When dyspnœa and vertigo set in after failure of compensatory hypertrophy, strychnine in small and frequent doses, in the author's opinion, best supports the heart's action, while the general tonic treatment should be used in conjunction. Thus iron, arsenic and vegetable bitters, together with heart-tonics, should be given.

The author regards digitalis still as "the" remedy when alarming dyspnœa and incipient dropsy make their appearance; but the digitalis or strophanthus should be withdrawn when beneficial results have been secured. But the nutrition of the heart is most steadily and greatly stimulated by small doses of strychnine. Small doses of nux vomica are also often administered with success. Caffeine is considered as more of a diuretic than a cardiac tonic. Coronilla is said to be slow in its action and not always certain.

The author sums up his experience in treating cases of valvular heart disease as follows:

Physical rest, associated with light, regular, pleasurable exercise; absence of all worry, mental anxiety and sudden emotion; plain, abundant, nutritious diet, as dry as possible; absolute avoidance of all stimulants; the use of general tonics and hydropathic measures conducive to the building up of the general constitution; for the heart, the continuous use of small doses of nux vomica or its alkaloid, reserving the more powerful heart stimulants, like digitalis, for threatened dropsy. In some cases better results were obtained from the combination of digitalis, strophanthus and convallaria than from either alone. In others it was found that either of these special heart-tonics alone produced the greatest comfort when assisted by minute doses of strychnine. It is bad treatment to use larger doses of any drug than is absolutely necessary; and ofttimes three to five drops of digitalis with $\frac{1}{100}$ or $\frac{1}{60}$ grain (0.6–1 mlgm.) of strychnine will act better than the larger doses of either alone. The use of strychnine alone is, in the majority of these cases, the best for prolonged treatment.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

EDITORIAL.

THE ORIGIN OF SEX.

There was once a notion that a woman by eating a lily, the symbol of purity, could become pregnant without the help of man. Notions as to the origin of sex having no more scientific or rational foundation have been held—indeed, positively declared as true. Thus Melanchthon, in the sixteenth century, asserted: "Males come from the right side of the womb and originate from semen from the right testicle. Females come from the left side of the womb."

Part of Melanchthon's theory was as old as Aristotle, who asserted that the right testicle produced boys, the left girls, and has told how Leophanos made the production of males or of females at will in his domestic animals by tying the testicle he wished to render sterile.

An old opinion still held by some asserts that the sex depends upon the relative preponderance or predominance of male or female at the time of fecundating coition. Debay has observed that this opinion, however satisfactory it may seem at the first glance, does nothing but point out the effect and is silent as to the cause. The words preponderance and predominance do not prove in what manner the ovum and the sperm, which have no sex, can give it to an embryo.

According to Mantegazza, the theory just mentioned has been upheld by the Chinese. They say that if the strong principle, *yang*, dominates in the male and the feeble principle, *yu*, in the female, a boy is born, while a girl comes in opposite conditions.

Debay maintained that the determination of male and female depended upon the greater or less nitrogen contained in the material of which the ova and the zoösperms are formed. In order that a male may be begotten the wife must for twenty or twenty-five days be restricted to substantial and nitrogenous food. With-

out mentioning the details as to her diet, we state that the author directs for the husband an opposite regimen—in fact, for the time he becomes a vegetarian. The last (the 166th) edition of Debay's work, "Hygiene et Physiologie du Marriage," was published in 1893, and the first twenty years before. We have quoted the directions more especially because a somewhat similar regimen for the same purpose was recommended two or three years ago by a German physician in the *Centralblatt f. Gynäkologie.* Echoes are more numerous than voices!

Thury's law determining sex in animals has not been proved to hold in human beings. A French physician, Mestivier, has stated that woman furnishes a male ovum one month and a female the next. Now, observing what month the first child is born in, the sex of subsequent births can be predicted, for supposing the child to be born in January and male, January and alternate months are male months for that mother, while girls will be born in February and its corresponding alternate months; properly the male month or female will be nine months before the birth.

Of course it is well known that the proportion of boys to girls is about 106 to 100, and that this preponderance is less in cities than in the country. It has been suggested that the excess of male births is in part to be attributed to the fact that in almost all families a son being desired, once such birth occurs, Malthusian moral restraint is invoked so that there is no more increase in the family. Physiology is utterly silent as to why more males than females are born.

In old primiparæ the excess of male births greatly increases, 140–160 to 100. It has also been observed that in new colonies in which not only young women, but also those that are old, readily marry, male births are also in great excess.

From some writer whose name escapes us for the moment we have the following statements: "A hundred ewes extremely well fed will produce a larger percentage of ewe lambs, while a hundred ewes poorly fed will produce a larger percentage of rams. After a war or a famine there are more human males born; in times of plenty and in the upper circles, more females."

In Drummond's "Ascent of Man" we find the following: "Starting with the function of nutrition as the nearest ally of reproduction, the newer experimenters have discovered cases in which sex has been apparently determined by the quantity and quality of the food supply. And in actual practice it has been found possible, in the case of certain organisms, to produce either maleness or femaleness by simply varying their nutrition—femaleness being an accompaniment of abundant food, maleness of the reverse. When Young, to take an authentic experiment, began his observations upon tadpoles, he ascertained that in the ordinary natural condition the number of males and females produced was not far from equal—the percentage being about 57 female to 43 male, thus giving the females a preponderance of 7. But when a brood of tadpoles was sumptuously fed the percentage of females rose to 78, and when a second brood was treated even more liberally the number amounted to 81. A third experiment with still better food gave 92 females and only 8 males.

Undoubtedly these and similar experiments will bring some light to one of the darkest problems in physiology, the origin of sex in the human race, but that they will drive away all the darkness we may doubt.

The Source of Danger.

Doctor—You mustn't stay out late at night.

Patient (a married man)—Is the night air bad for me?

Doctor—No; it's the excitement after getting home that hurts you.

ABSTRACTS.

DIAGNOSIS OF DIPHTHERIA.

Special announcement from the Laboratory of Bacteriology of the Philadelphia Polyclinic. As the early diagnosis of diphtheria from other pseudo-membranous affections of the throat has always been a matter of difficulty and in some cases of absolute impossibility, the consensus of opinion is that it can be made with certainty only by a bacteriologic demonstration of the presence or absence of the Klebs-Loeffler bacillus. Furthermore, the question of the association of other pathogenic and of pyogenic microbes with the Klebs-Loeffler bacillus is of importance in prognosis. In view also of the introduction of the blood-serum therapy, an early and absolute diagnosis is imperative in testing the efficacy of such treatment.

The Laboratory of Bacteriology of the Philadelphia Polyclinic is ready to undertake this examination and to report to physicians the bacteriologic diagnosis of suspected cases. Sterilized swabs and blood-serum tubes, together with instructions for the method of procedure, can be obtained at the laboratory or from Mr. W. S. Leffman in the faculty's office. The results of the examination will be reported within twenty-four hours from the time of the return of the tubes. *This service is gratuitous.*

TREATMENT OF GASTRIC ULCER.

Milk has been and still is the most important dietary food for patients suffering from gastric ulcer. Rest, as in most diseases, is another principal factor in the treatment. Dr. M. Einhorn describes the Leube-Ziemssen "rest cure," now so popular in Europe, as follows:

The patient is kept abed for two to three weeks. He is poulticed during the day with flaxseed (warm) over the stomach and the upper part of the abdomen; at night a priessnitz (wet linen cloth) is applied over the same area.

The diet consists of liquids—milk, milk with strained barley, oatmeal or rice water, plain water, weak tea and peptone (one teaspoonful to a cup of water). During the first week the patient takes half a cup (about 100 c.c.) of either every hour. Everything the patient takes must be neither very cold nor very warm, and should be taken slowly (sipping or with a spoon). During the second week the patient is given the same kind of food, with the only difference that he is fed every two hours, and a cupful or a cupful and a half (200 to 300 c.c.) is given at one time. In the beginning of the third week the patient is fed every three hours; he is allowed barley, farina and rice (well cooked) in milk, soft-boiled eggs, crackers softened in milk—in addition to his previous food; on the third day of the third week the patient begins to partake of meat—first raw, well scraped, then broiled. Thereafter the patient is put upon the ordinary daily diet—excluding heavy salads, pastry, raw fruit and the like.

At the beginning of the third week the flaxseed poultices are discontinued and the patient is allowed to be up—first for a short time only (one-half an hour to an hour), then for several hours, and thereafter for the whole day. At the beginning of the fourth week the patient may begin to walk outdoors and slowly resume his wonted occupation.

Whenever the pains become associated with frequent vomiting or hæmatemesis, the author orders the patient to abstain from any food whatever, given by the mouth, for a period of five days. The patient is then fed by the rectum in the following way: Early each morning the patient receives a large enema of about a quart (or liter) of lukewarm water in which a teaspoonful of common table salt has been dissolved (cleansing enema).

About an hour after the patient has voided the injected water the first nourishing enema is given; the same may consist either of a glassful of milk (about 200 c.c.) in which a raw egg has been well beaten and a pinch of salt added, or of a cupful of water in which a tablespoonful of a good peptone preparation has been dissolved. The temperature of either must be about 100° F. (38° C.). Such a nourishing enema is given three or four times a day. The quantity of the feeding enema is 200 to 250 c.c., and it is slowly injected by means of a fountain syringe and a soft-rubber rectal tube. The patient frequently rinses his mouth with cold water, and is allowed from time to time to keep a small piece of ice in his mouth and to swallow the melted water. The five days being over, the mode of diet is the same as described above for the ordinary form of ulcer. In cases of hemorrhage from the stomach, the treatment is the same as in the severe type of ulcer, with the only exception that ice-cold applications are made over the stomach instead of warm poultices.

The author is of the opinion that there is, after the application of the "rest cure," hardly any need for constant medical treatment. Sometimes, however, he makes use of a small dose of codeine if the pains are very severe, and of Carlsbad salt if there is constipation. Only in cases where the ulcer is associated with a hyperacid gastric juice, he regularly prescribes an alkaline salt, as, for instance:

Calcined magnesia		1 part
Sodium carbonate	āā	3 parts
Sodium bicarbonate		
Peppermint oil sugar		

A tip of a knifeful every two hours.

The author then reverts to the two methods he employs for those patients who cannot undergo the "rest cure." One is the silver nitrate treatment, the other the bismuth treatment. In applying either of these two measures, the patient is allowed to attend to his business and partake of a light diet in which milk plays a great part.

1. The silver nitrate is given first.

Silver nitrate	0	3 gm.	grs. ivss
Distilled water	180	0 "	fl℥ vj

Dispense in a black bottle.
A tablespoonful in a wineglassful of water three times a day half-hour before meals.

After having used up this quantity the dose may be gradually increased—prescribing 0.4 to 0.6 gm. (6–9 grs.) of silver nitrate to 180 gm. (6 fl. oz.) of water. The silver nitrate may be used in the way mentioned for about two or three weeks and then discontinued. The pains, it is stated, usually disappear after the first week's medication.

2. In the bismuth treatment 3 to 5 gm. (45 to 75 grs.) of the subnitrate are given to the patient three times a day, suspended in water, half an hour before meals. It is best to have the patient lie quietly for about half an hour after having partaken of the powder. The bismuth treatment must be continued for about two or three weeks without interruption.

It is remarkable that these large doses of bismuth do not, as a rule, cause constipation. In all of the author's five cases the bowels moved every day without the aid of any cathartic during the whole time of the bismuth medication; and in four the latter proved very beneficial.—*Med.-Surg. Bull.*

Formalin for Chancroids and Venereal Warts.

Gaylord having tried formalin as a local application is a series of cases of this kind, reports (*Med. News*) his results as uniformly favorable. The best results are obtained by using full-strength solutions, and then one application is usually sufficient. The pain produced by the full strength (40 per cent.) is not markedly greater than that produced by any solution above 10 per cent. Pain, while excessive, can be deadened by cocaine, when it is probably not more severe than that caused by nitric acid. The drug should not be applied over large surfaces except in weak solution. When continued for a protracted period of time it tends to cause an intolerance on account of the pain produced.

Pruritus Ani Successfully Treated with Chlorinated Lime.

N. K. Berger (*Zemsky Vratch*) inserts into the anus, about one inch deep, a pledget of cotton soaked in liquor calcis chlorinate, which is left there until smarting occurs, when it is withdrawn and the anus bathed with the same solution. The operation is to be repeated. Swelling of the parts, concomitant dermatitis or eczema are said to be cured by a few applications.

THE NEW FIGHT AGAINST CHILDREN'S DISEASES.

Whereas in European cities the battle of the municipal and health authorities, so far as epidemics were concerned, was until a few years ago waged chiefly against small-pox, typhus and occasional outbreaks of cholera, it is now considered that the victory has in the main been won against these bolder and grosser enemies of the race, and the conflict has set in against the diseases which are hostile to child life. Scarlet fever and diphtheria are the chief of these children's maladies, with measles as a less dreaded but extremely mischievous third. Thus far the weapons have been mainly those of vigilant, never-ceasing inspection, immediate isolation, disinfection through the aid of highly organized official disinfecting staffs, and in general the sharp blocking up of those avenues through which infection is most likely to be communicated. The difficulty of perfect isolation in tenement-houses has led to the great extension of public hospitals for the reception of children ill with diphtheria, scarlet fever and measles. The great objects of the administrators of the public-health system are (1) to abolish the plague-spots which are the sources of infection and (2) when infection has appeared to prevent its spread. This of course is the sound policy to be pursued. But, (3) and concurrently, every possible effort is made to save the lives of the poor children actually seized with infectious maladies. If we are rightly informed with regard to the anti-toxine cure for diphtheria, its application is to be beneficial both as a preventive against attack and also, where not previously applied, as a remedy to be administered in the early stages of the disease. Its immediate interest naturally lies in its use as a remedy. A considerable amount of experience, tested in the light of comparative statistics, would be necessary in order to show the preventive value of such treatment, and even then it would be difficult to distribute the honors between a remedial specific of this kind and a generally efficient sanitary administration. As in the case of vaccination, no one could ever tell us conclusively what part the particular treatment has played, and what part improved conditions of public and private cleanliness have had in the gratifying diminution of the malady.

LONG-LIVED AMERICANS.

This Western hemisphere has many sorts of climates, but they all have in common this encouragement, in exceptional cases it is true, to great age. It has been supposed that the exceedingly variable and violent climate of some regions of our country is hostile to long life. But if we study the matter in view of multitudes of instances, we see that it is not climate, or even hardship, that shortens life in the United States, for instance, but that it is worry and care, or, in other words, the furious pace at which we try to live. No attempt is made to defend the climate of New England, and yet the number of people who have attained a great age in it is positive proof that the climate is not altogether in fault for mortality. It is probable that the record would be very different if we had paid as much unworried attention to growing old as we have to fighting Indians, subduing forests, making money and getting ahead of our neighbors. We are still as a nation very young, some physical conditions have been against us, and there has not yet been time enough to spare to show what the country can do for us in the way of longevity. In New England they are less than three lives from the landing of the Pilgrims. Among the Pilgrim records at Plymouth is a letter from Peregrine White, who was born on the *Mayflower* when it lay in Provincetown—the first white child born in New England. Following that is a letter from an estimable Pilgrim deacon, who lived to be 106 years old, and who testifies that he knew Peregrine White. Following that is a letter from a lady still living, at the age of 92, who says that she remembers the aged deacon of 106 years. Thus less than three lives takes us back

to the Landing and to the Rock, which is almost as mysterious as the aerolite, or black stone, in the Kaaba at Mecca, since it is like no other piece of granite on the Massachusetts coast. It may be mortifying to see that we have no greater antiquity than this, but the efforts of three persons to cover it is encouraging.

But it is in other regions of the continent that we must at present look for the extraordinary capacity of the New World for producing old people. Well-authenticated are cases of mission Indians in southern California who reached the ages of 120, 130 and 140. In that equable region all the great functions of nature go on with regularity, so as to induce a long running of the machine. But besides this, these old men were probably free from care, from religious doubts and skepticism and political worry and ambition, and it is testified that they were simple in their habits, temperate, and even abstemious, drinking only water and eating little but corn, which they fitted for digestion by the vigorous action of their own grinders. Lieutenant Gibbons found in a village in Peru 100 persons over the age of 100, and either he or another credible explorer there reports another man aged 140. He was a very temperate man, ate his food cold and never ate meat except in the middle of the day. In the highlands of South America the habit of old age is a long-established one. In Ecuador centenarians are common. The census of 1864 found in the town of Pilaguin, 11,000 feet above sea-level, about 2,000 inhabitants, among whom were 100 over 70 years of age, 20 about 80, 11 over 90, 5 over 100 and 1 who was 115. Not many years ago there died in Ambato a woman named N. Cucalou, who was 114, and one Don José Soto aged 120. In the year 1840, in the town of Baños, died old Morales, a vigorous carpenter to the end of his life, who was well on in years and the steward of the Jesuits when they were expelled from their property in 1767. In 1838 a witness in a judicial trial was proved to be 140 years old, having been born on the night of the great earthquake which destroyed the old town of Ambato in 1698. How much longer this man lived, who was cradled by an earthquake, is not yet reported. Mexico, notwithstanding its revolutions, is equally favorable to longevity. In the State of Vera Cruz there died a man in 1893 who was 137 years old. That he was carried off prematurely we have reason to suppose, for at Teluca, where the register is officially and carefully kept, there died only a few years ago a man aged 192.—*Harper's Magazine.*

Public Health Service.

Whatever then may be the merits of anti-toxine as a cure for diphtheria, there can be no mistake in the policy of public cleanliness and of constantly improved health administration. Our American cities come short of their European contemporaries in most points of municipal organization and service. Fortunately, in the matter of public health work we have less to be ashamed of than in almost any other particular. There have been some scandals in the Health Department of New York City, but there has been very much to commend. All that is needed to bring our American municipal health administration up to a point of scientific and practical efficiency equal to that of the very best managed foreign cities, is a reform of our municipal government in general respects. The work of health boards is necessarily hampered at many points by the existence of corruption, of spoils methods and of ignorance and inefficiency in other departments of city government.—*Review of Reviews.*

The Treatment of Hemorrhoids.

Dr. Claude A. Dundore has an interesting article on the treatment of hemorrhoids in *Mathew's Quarterly* in which he presents the following conclusions, based upon a large correspondence with American surgeons:

1. The ligature is the safest method, as there is less likelihood of its use being followed by hemorrhage, strictures, or ulcers.

2. The clamp and cautery causes less pain and a shorter convalescence, but hemorrhage and stricture of the rectum may very often follow its improper application.

3. Whitehead's method should be limited to those cases in which the entire circumference of the anus is involved. In ordinary cases of one or more hemorrhoids it should never be used.

4. Simple dilatation of the sphincter, injection of carbolic acid and Manley's method are merely palliatives.

SOCIETY REPORTS.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of December 3, 1894.

Dr. H. R. Wharton exhibited

A DUMB-BELL-SHAPED CALCULUS WHICH HAD BEEN PARTIALLY ENCYSTED REMOVED BY LITHOTOMY.

This calculus was removed from a child five or six years of age. I show it, as it is of interest in connection with the choice of operation for the removal of calculi from the bladders of children. This patient was brought to the Children's Hospital and on examination I found a stone in the bladder. I hesitated some time as to what operation I should make use of. I was inclined to do litholapaxy, but when the child was etherized I made a rectal examination and felt a prolongation of the bladder into the rectum containing the stone. I decided then upon lateral lithotomy, and after exposing the stone and attempting to grasp it, I found that it was impossible to remove it, as the posterior portion was thoroughly surrounded by the walls of the bladder. I dissected it out with my finger without breaking it. The patient after the operation did perfectly well. I believe that in a case of this kind it would be impossible to do litholapaxy, for while the projecting portion of stone could have been grasped and crushed, the encysted portion could not have been reached.

I have had very little experience with these partially encysted stones, but in two of the cases that I have recently seen I have found that a great deal can be learned by rectal examination. In the previous case I was able to make up my mind pretty clearly as to the shape and possible attachments of the stone. I show the specimen mainly for the purpose of calling attention to the difficulty of crushing stone under such circumstances. I have done litholapaxy in a child five years of age. The operation is a satisfactory one if you can completely crush the stone. In the case mentioned I used a No. 16 lithotrite and had no trouble in crushing and removing the stone. The day after operation the urine was clear and the temperature was normal. The patient made a satisfactory recovery. Some time ago I assisted a friend in a suprapubic lithotomy where much the same conditions were present as in the case which I have reported, the posterior portion of the stone being imbedded. In such a case the attempt to do litholapaxy would have resulted in an incomplete operation.

DISCUSSION.

Dr. J. Ewing Mears: Dr. Wharton has presented a very interesting question. I think the experience of lithotomists points to the view that in children and in elderly persons the cutting is a safer one than the crushing operation, for the reason that in children the urethra and bladder being small, there is some difficulty in the manipulation, and in elderly persons there is danger in many cases of disease of the bladder or kidneys.

It will be remembered that when Napoleon III was operated upon for stone by crushing and death supervened, the question was largely discussed, and it was thought if lithotomy had been performed in his case the result might have been different.

Dr. Thomas S. K. Morton: As bearing upon the question of the choice of operations, it may be of interest to recall an article which recently appeared upon the subject of litholapaxy in children by Surgeon-Major Keegan. Major Keegan believes that litholapaxy is the ideal operation in children, where one can drill himself properly in the procedure, but that for those who have occasion to operate but seldom, the cutting method is far safer. His statistics, running up into

hundreds of cases, show an astonishingly low mortality. Before adopting the crushing operation in children he had cut in innumerable cases. I think that this is the view that should guide us in this country, where few have an opportunity for extensive experience, as the affection is in most localities quite rare. Probably the cutting operation, either the left lateral or the suprapubic, will continue to be the safest operation for all save those who see many cases.

Dr. Wm. B. Hopkins reported

TWO CASES OF EXTENSIVE DESTRUCTION OF THE INTEGUMENTS WHICH WERE CURED BY TRANSPLANTING LARGE FLAPS.

(See page 91.)

DISCUSSION.

DR. J. EWING MEARS: I would like to ask Dr. Hopkins why, in the first case, he selected the Velpeau position rather than that at right angles? This would have given better opportunity for keeping the parts clean. An interesting point is in regard to the transplantation of large flaps to cover denuded surfaces about articulations. Both the elbow and the ankle in these cases show perfect preservation of function.

Some years ago I had under treatment a case in which a large denuded surface occupied the surface of the abdomen. It was the largest raw surface that I had seen up to that time. It followed a sloughing bubo from a non-infecting sore. When I was called to the case the ulcer reached from the crest of the ileum of one side to that of the other, and from the umbilicus to the pubes in the median line, and on the right side, where it had originated, it extended three or four inches down the anterior surface of the thigh. It required ten months for this surface to entirely close. The ulcer was finally covered with a cicatrix which was not very tense. Occupying the region it did, it was not so necessary that it should possess the properties which we see in the cases which Dr. Hopkins has presented, where the ulceration occurred in connection with articulations.

DR. HOPKINS: In reply to Dr. Mears I would say that it was desired to take the flap from the chest rather than from the abdomen, and in order to secure the requisite length of flap it was necessary to bring the arm approximately into a Velpeau position.

Penis Vegetations.

Dr. B. E. Vaughan (*Amer. Medico-Surg. Bull.*) points out that vegetations on the penis are spoken of as venereal warts, but there is no necessary relation between them and venereal disease. They are usually multiple and may be pedunculated or flat. They are caused by the presence of irritating fluids or by simple lack of cleanliness; consequently they are usually associated with gonorrhœa or balanitis. Their usual seat is behind the corona glandis, on the inner surface of the prepuce and at the meatus. They may be few in number and small or large and numerous. Besides the uncleanliness and annoyance, their greatest danger consists in their possible change to malignant growth in the aged. Circumcision, with the removal of the wart-producing surface, is advised. If that is not practicable, use of the galvanic cautery after the warts have been removed with scissors, or the use of nitric acid followed by drying powders, *e.g.*, equal parts of boric acid, bismuth and calomel. If the warts are flat we may apply corrosive sublimate 1 dram to collodion 1 ounce.

Copper Arsenite in Therapy.

A number of cases are described by Dr. A. Hedlicka in which he employed copper arsenite locally, with almost universal success in the various acute and sub-acute inflammations of the mucous membranes, attended with pain, suffusion and more or less watery discharge. He found it most efficient in solutions of 1:50,000–100,000. These solutions are easily made by dissolving a $\frac{1}{100}$ grain pellet in $1\frac{1}{2}$ ounces of water; they are applied at intervals rarely longer than an hour (bladder, urethra and nose), and frequently not longer than from ten to fifteen minutes.

The remedy is rather indifferent in cases where the discharge is thick or persistent unless the affected surface be previously thoroughly cleansed.

The duration of the treatment ranged from a few hours to two or three days in mild cases, from several days to three months in severe cases. The author pretends to have never failed; relief being nearly always instantaneous, no other remedies were needed.—*N. Y. Med. Jour.*

THE LIBRARY TABLE.

BOOK REVIEWS.

ORGANIC MATERIA MEDICA AND PHARMACOGNOSY. By Dr. Lucius E. Sayre, Dean of the School of Pharmacy, University of Kansas. Philadelphia: P. Blakiston, Son & Co., publishers. 1895.

The work begins with a condensed but quite thorough discussion of structural botany, including vegetable histology. There follows a list of drugs,—officinal being distinguished from non-officinal by capitalization—classified according to the part of the plant, root, stem, leaf, etc., from which they are derived. When such a classification cannot be made the drug is distinguished as being an extractive, saccharine substance, mucilage, resin, etc. Then follows a description of drugs according to their arrangement in natural botanical orders, ending with a few animal drugs. Appendix A treats of insects injurious to drugs and Appendix B of organic chemicals prepared artificially. The work is copiously illustrated with 543 cuts, mostly original, and a system of numbering provides for ready reference from one part to another. As the book is designed more for the pharmacist than for the physician, only the briefest allusion is made to the action of remedies. The work is admirably adapted to be used as a combined text-book of materia medica, pharmacognosy, botany and microscopy in pharmacy colleges.

A. L. B.

TRAVAUX D'ELECTROTHERAPIE GYNECOLOGIQUE. Archives Semestrielles d'Electrotherapie Gynecologique fondees et publiees. Par le Dr. G. Apostoli, vice-president de la Societe Francaise d'Electrotherapie, etc. Vol. i, fascicules i et ii. Paris, 1894.

Dr. Apostoli, who may justly be termed the father of electrical gynecology, has in the present work undertaken a task of almost Herculean proportions Employing his own words, he has attempted to unite into one compendium, of which the present book is but the first volume of two fasciculi, all of the most important contributions that have from time to time appeared upon this subject. He has commenced the work by presenting some of the most important foreign contributions, all of which have been translated into French especially for this purpose. The succeeding volume likewise is to contain papers prepared by other than French writers, and the closing fasciculi are to be devoted to the contributions of eminent French electricians. A valuable feature of the work is to take the form of an appendix containing a complete bibliography of the subject. Dr. Apostoli has been induced to attempt the publication of a work of this magnitude in the hope that the cause of conservatism in abdominal surgery may be materially furthered, and that the number of useless and dangerous mutilations of the female genitalia may be considerably diminished. The material of the present volume is drawn from the pens of English, American, Russian, German, Canadian, Austrian and Italian authors, and includes the work of such eminent men as Lawson Tait, Thomas and Skene Keith, W. S. Playfair, Ephraim Cutter, Grailly Hewitt, A. Lapthorn Smith, Franklin H. Martin, G. Betton Massey, A. J. C. Skene, Paul Munde, Massin, Candia, Klein, Mandl and Laforest. It will be interesting to follow the successive volume of this work.

W. D.

PRACTICAL URANALYSIS AND URINARY DIAGNOSIS. By Charles W. Purdy, M.D., Queen's University. Philadelphia: The F. A. Davis Company, publishers. 1894.

Dr. Purdy calls his book a manual. In reality it should be called a text book, for though in description it is terse and concise, on close inspection it will be found full and complete. The great value of the book lies in the fact that the clinical significance of all substances found in the urine is brought in great prominence—a thing which has been neglected, or rather overlooked, in all the text-books on this subject that have been brought before the medical profession.

The writer has devised a new method for testing for albumin. It consists in the addition to the urine of salt solution until the specific gravity of the urine is raised ten or fifteen degrees. Next add to this solution in a test-tube two-thirds full one or two drops of strong acetic acid and boil the urine in the upper part of the tube. If albumin is present the upper part of the tube will be turbid, in contrast with the clear portion below. This test he regards as being the most accurate of all albumin tests. Second to it is the ferrocyanide test.

The author describes his own electric centrifuge for the precipitation of urinary sediments, the advantages of which are as follows: 1. It permits immediate examination. 2 Sedimentation is more complete and concentrated. 3. It affords a positive method for distinguishing between normal and abnormal crystalline sediments. 4. Micro-organisms like tubercle bacilli are found with greater ease and certainty.

There has been added a chapter, unique in that it has never before appeared in any work on the subject of the urine, and that is the examination of the urine for life insurance. The reason for this is very palpable. In spite of the fact that many companies issue minute instructions in regard to examination of the urine, a very large percentage of unprofitable risks arise through diseases of the kidneys which have escaped detection. He says that minute quantities of albumin are often observed in the urine of men at and beyond middle age who not only appear perfectly healthy, but who have, as a matter of fact, enjoyed the most typical robust health all their lives. The reason for this is that

chronic Bright's disease is nearly always the sequel to a robust life, the kidneys being the first organs to fail under the pressure of long-continued activity in the elimination of waste products which are excessive in those of great appetite and ample nourishment.

J. O.

LANDMARKS IN GYNÆCOLOGY. By Byron Robinson, B.S., M.D. The Physician's Leisure Library. Detroit, Mich.: George S. Davis. 1894.

This book is not a pretentious work on gynæcology; it simply deals with its "landmarks," such as anatomy, menstruation, labor, abortion, gonorrhœa and tumors.

Under anatomy the author describes the peritoneum and its inflammations, laying special stress on the points where inflammations begin, such as the Fallopian tube, appendix, etc.

Gonorrhœa and its widespread effects on the female genitalia are dealt with at full length on account of its importance, for every practitioner of medicine can call to mind cases in his own practice illustrating the fearful ravages of this disease.

The author has a very simple, and for practical purposes a very easy, classification of tumors, as follows:

I. Cysts.
II. Epithelial tumors.
III. Connective-tissue tumors.
IV. Dermoids.

He describes a new operation consisting "in ligating the tubes and ovaries (with removal if indicated) and ligation of the uterine artery as it courses along the sides of the uterus. The indications for the operation are (1) to avoid the removal of uterine myomata; (2) to aid in causing atrophy of the myomata; (3) to induce cessation of menstruation; (4) to check uterine hemorrhage. This operation will cut off the chief blood supply of the fundus of the uterus, and by it the shock attendant on hysterectomy, which is so often fatal in very anæmic patients, will be avoided." O.

A HAND-BOOK OF MEDICAL MICROSCOPY. By James E. Reeves, M.D. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut Street, 1894.

We have in this brief work a careful summary of the advantages of the microscope for use by the physician, who is informed, first, as to its importance in medicine, next what to buy when providing himself with an outfit, and how to go to work. The subject of bacteriology is well treated in a small space. The micrococcus Pasteuri is preferred to the pneumobacillus as being the true factor of the disease in croupous pneumonia. The examination of neoplasms is discussed at length, and the discussion contains just the amount of information required, without confusing the reader with unnecessary details. In examining the blood the author gives the stains that have but recently been brought into use He brings the book well up to date so far as medical progress is concerned.

J. O.

THE MEDICAL NEWS VISITING LIST for 1895. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 160 pages of blanks. The 60-patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, with pocket, pencil and rubber. Seal grain leather, $1.25. Philadelphia: Lea Brothers & Co. 1894.

The Medical News Visiting List for 1895 has been thoroughly revised and brought up to date in every respect. The text portion (32 pages) contains useful data, including an alphabetical table of diseases, with the most approved remedies and a table of doses. It also contains sections on examination of urine, artificial respiration, incompatibles, poisons and antidotes, diagnostic table of eruptive fevers and the ligation of arteries. The classified blanks (160 pages) are arranged to hold records of all kinds of professional work, with memoranda and accounts. The selection of material in the text portion and the arrangement of the record blanks are the results of years of experience and special study. Equal care has been bestowed upon the mechanical execution of the book, and in quality of paper and strength and beauty of binding nothing seems to be wanting. When desired, thumb-letter index is furnished, which will save many-fold its small cost (25 cents) in the economy of time effected during a year. The list adapts itself to any system of keeping professional accounts.

INTERNATIONAL CLINICS: A QUARTERLY OF CLINICAL LECTURES ON MEDICINE, NEUROLOGY, PEDIATRICS, SURGERY, GENITO-URINARY SURGERY, GYNÆCOLOGY, OBSTETRICS, OPHTHALMOLOGY, LARYNGOLOGY, OTOLOGY AND DERMATOLOGY. Volume I, fourth series. Philadelphia: J. B. Lippincott Company. 1894.

This volume represents the collaboration of forty-two contributors, among whom are such men as Byford, Chapin, Cohen, Hunter McGuire, Mills, Rosewell Park, Hare, Sayre, Skene and Von Noorden, of Berlin.

The volume opens with an interesting memoir of Professor Charcot, written by M. Allen Starr and accompanied by an excellent lithograph of the distinguished physician and clinician.

Among the more interesting and strongly written articles are "The Treatment of Rheumatism," by A. Ernest Sansom, M.D., F.R.C.P.; "Pernicious Anæmia," by W. Hale White, M.D., F.R.C.P.; "Pott's Disease," by Lewis H. Sayre; "Affections of the Lachrymal Gland," by Simeon Snell, M.D., F.R.C.S. Edin.

Dr. Sansom defines rheumatism as "a morbid process whose manifestations are chiefly in the serous membranes of the joints, in the pericardium, endocardium, pleura and sometimes in the fibrous tissues in various situations (rheumatic nodules)" . . . "it is very rarely manifested for the first time after the age of thirty-five." He calls attention to the widespread fallacy that all painful affections of the joints are rheumatic, and mentions as

instances the non-rheumatic arthritis of blood deterioration and blood extravasation, as in scurvy, purpura, hæmophilia and the infective diseases, as syphilis, typhoid fever, gonorrhœa, influenza and scarlatina. He believes that the disease is due to a disturbance of metabolism whereby certain undetermined toxines are elaborated. His treatment of rheumatism of the joints is summed up in the use of the salicylate of soda, and in cases involving the heart the application over the præcordial region of the ice-bag. In protracted cases of rheumatism of the heart and its membranes he recommends the continuous galvanic current from the nape of the neck over the course of the great nerves in front of the neck for six minutes thrice daily, believing it to act upon the trophic mechanism of the heart.

"Pernicious Anæmia," by W. Hale White, is instructive, and he describes three cases in detail of this rare affection, one of which went to post mortem. He calls attention to the fact that the profound anæmia of obscure malignant disease, as of phthisis, is not infrequently confounded with pernicious anæmia.

The detailed report of these cases seems to disprove the belief that in this disease the percentage of red corpuscles always falls below the percentage of hæmoglobin. The only constant pathology at post mortem is an increase of iron in the liver, and if we cannot find this increase our diagnosis must have been incorrect. In one of his cases the iron amounted to over 1 per cent., or about twelve times the normal quantity.

Prognosis is always grave, even though temporary improvement is not uncommon. In two cases, however, the patients were apparently free from the disease at eleven years and four years respectively after treatment had been instituted.

Dr. Sayre, in his article on Pott's disease, emphasizes the mistake which many physicians make in treating this affection by the plaster-of-paris jacket in children under three years of age, as their narrow pelves give no support. The proper apparatus is the padded cuirass and jury-mast. He calls attention to the very practical point that in this disease the pain at first is often not in the back, but in the stomach, so that the case has been treated as one of indigestion.

Dr. Simeon Snell's chapter on "Affections of the Lachrymal Gland" describes several very interesting cases of such rare affections as acute suppurative inflammation of the gland and of adenoma, with photographs.

Altogether the book is one of the best of the series and contains much of interest to the physician, surgeon and specialist.

W. H. P.

ESSENTIALS OF ANATOMY. Including the anatomy of the viscera. Arranged in the form of questions and answers, prepared especially for students of medicine. By Chas. B. Nancrede, M.D. Fifth edition, with an appendix on the osteology of the human body; the whole based on the last edition of Gray's Anatomy. One hundred and eighty fine illustrations. Philadelphia: W. B. Saunders. 1894. Price $1.00.

The increasing demand for a concise arrangement of such a vast subject as that of anatomy has resulted in the publication of a fifth edition of this admirably arranged compend by Dr. Nancrede, and the addition of an appendix containing a full set of osteological plates has increased the usefulness of the work to an extent which we are sure will fully repay the publisher for his extra outlay of time and expense. W. H. P.

Anxiety as a Cause of Granular Kidney.

It is interesting, in relation to the ailment of the late czar, to recall a paper read by Prof. Clifford Allbutt at the annual meeting of the British Medical Association at Sheffield in 1876. The subject he took up was "Mental Anxiety as a Cause of Granular Kidney," and by an analysis of his case-books he showed what an abnormally large proportion of the patients showing symptoms of granular kidney had been subject to the depressing influence of prolonged anxiety. He says: "During the last two years I find I have made notes of 35 cases of granular kidney occurring in private practice, and I find a marked history of mental distress or care, or both, in 24 of them." This is a large proportion even if we admit that the pushing inhabitants of West Yorkshire worry abnormally concerning this world's goods. Several illustrative cases are given, and one especially in which, as a consequence of an unfortunate investment, a man in a good position for three years "went to bed night by night ignorant whether he might not be gradually drained of his all." Dickinson is in some sense in accord with Allbutt on this question, although not so positive. Prolonged mental disturbance, anxiety or grief as a cause of granular kidney is, he says, "perhaps problematical; the mode of its operation is not obvious, but must be surmised as through the nervous system. A lowering of nervous force is to be recognized at least as predisposing to every form of albuminuria. I have seen so many instances in which granular degeneration has been immediately sequent upon trouble that, in the absence of other causes, I am fain to conclude that mental conditions are sometimes concerned in its production."—*Brit. Med. Jour.*

Digital Compression of the Pneumogastric in Paroxysmal Tachycardia.

Dubois (*Sem. Med.*) has successfully employed digital pressure over the carotid region in a case of paroxysmal tachycardia. The patient was a woman, fifty years old, of nervous temperament, who suffered from frequent attacks of tachycardia, which lasted from five to fifteen hours and often terminated in collapse. In one of these attacks the author displaced the carotid a little toward the median line and made firm pressure over the pneumogastric area, with the result of reducing the cardiac pulsations from 140 to 96 per minute. The seizure was effectually controlled in ten seconds. Moderate compression is sufficient; too forcible pressure over the carotid region may produce syncope.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE BOSTON MEDICAL AND SURGICAL JOURNAL.

Dr. George F. Jelly reports a case of

Mental Shock.

The victim was a married man, thirty years old, abstainer from liquor and tobacco, never subject to venereal disease and free from marked heredity to disease. He was usually in good health, but was nervous and excitable.

While walking one day on the railroad track his foot caught in an electric wire, and after falling he was barely able to throw himself outside the track in time to escape an approaching express train which passed a few inches from him. He rose and went home uninjured but somewhat excited, became rather more nervous in detailing the occurrence, slept poorly, woke early in the morning, seeming startled, and found himself unable to speak.

When seen the patient had marked tremor of the lips, tongue and hands, and on attempting to stand a tremor of the legs developed and made him unable to support himself.

Careful examination showed nothing abnormal, the pupillary and other reactions were normal, and ophthalmoscopic examination was omitted.

Any noise, particularly that of a railroad train, caused increase of disturbance and made the patient tremble as if afraid. The mind seemed to act sluggishly, but conversation was evidently understood.

By degrees improvement took place in all the symptoms and became more rapid as it progressed, until it was discovered about a year and a half after the accident that no occurrence that had taken place in the interval had made enough impression on the patient's mind to be remembered.

Improvement in memory began, so that the man could by degrees remember the occurrences of the previous day, then two days, etc., until finally he is able to remember some things that took place six months ago.

Suit was brought against the railroad on the ground that the wire was not properly placed, but was disallowed on the ground that the plaintiff had not exercised due care when on the track. No question of the genuineness of his condition was raised. He is still unfit for any work placing responsibility on him.

Osler divides these cases into simple neurasthenia, cases with marked hysterical manifestations and cases with severe symptoms indicating or simulating organic disease.

Other articles in this issue are "On the Occurrence of Lead in City Drinking Waters," by Dr. William B. Mills; "Cases Illustrative of the Diagnostic Value of Examination of the Blood," by Dr. Henry Jackson; "Some Observations on Tubercular Meningitis," by Dr. A. E. Austin.

IN THE PHYSICIAN AND SURGEON

for November Dr. Carl Bonning writes of

Appendicitis: Its Medical and Surgical Treatment.

The writer has had recoveries of about 80 per cent. of cases under the following treatment, without operation.

A diagnosis of probable appendicitis being made the patient is put to bed, with an ice-bag in the ileocœcal region. An attempt is made to move the bowels by a laxative if they have been constipated, but if mild measures are not successful no further attempt is made.

For the relief of pain powdered opium is given, and one-quarter of a grain every hour or two, gradually reduced to a quarter of a grain every three or four hours, is usually sufficient. A hypodermic injection of morphine sometimes seems preferable to the opium.

If under this treatment the symptoms abate the ice-bag will become irksome and may be laid aside, the strict liquid diet may be gradually increased, and if no movement of the bowels has taken place by the twelfth day an enema or a dose of oil may be given.

While giving due credit to this treatment, the author thinks it is apt to result in recurrent attacks, and favors surgical interference at a convenient time between attacks. When an operation is performed the appendix should be found, if possible, and removed.

Dr. F. Maas reports a

Case of Operation for Substernal Tumor.

The patient was a multipara, forty-six years old, who had suffered for six or seven years from attacks of dyspnœa caused by a goitre.

While awake the breathing was comparatively easy, but when asleep the dyspnœa became so great as to awake the patient or to lead members of the family to arouse her.

The veins over the tumor were enlarged to about the size of the little finger, and during the operation, in spite of double ligatures and hæmostatic forceps, the bleeding was very free from the entire surface of the tumor and led to the fear that the patient would die on the table.

While making traction on the mass a lobe about the size of a hen's egg was drawn from behind the sternum, relieving venous pressure, stopping the hemorrhage and exposing the great vessels of the neck on the left side.

To avoid myxœdema the smaller portion of the growth on the right side was left undisturbed.

Owing to the bleeding the antisepsis had necessarily been imperfect and therefore compresses were used instead of sutures. The post-sternal pocket healed by granulation, and recovery without complication resulted.

Although exophthalmos existed in this case prior to operation, the author does not report this as a case of Graves' disease, believing the symptom due to the mechanical effect of the humor on the veins of the neck. He calls attention, though, to the fact that diarrhœa and disturbed menstruation which were present were cured. He has seen cases of undoubted Graves' disease cured by operation, and thinks all cases of goitre which cause annoyance and are not relieved by medication, or which show areas of hardening, or which suddenly begin to increase in size after a period of inaction, should be extirpated.

Oher papers in this issue are "The Treatment of Congenital Clubfoot," by Dr. George S. Ney, and "The Doctor in Politics," by Dr. Frank S. Hough.

THE TEXAS SANITARIAN

for December. Dr. W. T. Baird writes of

Oxygen.

Oxygen he thinks one of the best heart tonics. The blood absorbs the gas, and the heart, being the first active muscle with which this comes in contact, is enabled to appropriate it first.

To benefit from this a muscle must be in action at the time the gas is present, and that active muscles derive increased energy from its absorption the writer points to the athlete in contrast to the student, to the wolf, cat and draught ox in contrast to the stalled ox and hog.

Wallian is quoted as claiming that no remedy has given such good results, even in organic heart disease, as oxygen, in his experience

In preparing the oxygen the author uses the mixture of chlorate of potash and dioxide of manganese, and in administering the gas dilutes it with from 20 to 50 per cent. of air. The directions given are to inhale the gas forcibly, not oftener than once in five minutes, and the periods of inhalation are distributed as uniformly as possible throughout the day.

A series of cases is given illustrating the effect of oxygen in various kinds of disease.

IN THE BRITISH JOURNAL OF DERMATOLOGY

for December Dr. H. Leloir concludes his article on

Dermato-Neuroses and Their Treatment.

The first point to be observed in treatment of these affections is to prevent contact with the air and to avoid local infection and mechanical irritation. In carrying out this treatment exclusive dressings are prepared by spreading ointments or pastes thickly on linen and covering the whole by gloves or wadding, or else use is made of gelatine, medicated varnishes, etc.

In the treatment of severe prurigo scarification, or else the making of numerous fine punctures with needles, is often successful where there is rapid formation of œdema or perifollicular congestion. Vasomotor constrictors, such as alcohol and alcoholic solutions of ergotin and ichthyol, are often useful, and so is counter-irritation by cautery, iodine, ethyl chloral spray, etc., along the spine or nerve tracts.

The continuous electric current has proved useful in a number of affections, particularly morphœa and vitiligo. Both the continuous and the interrupted currents may be used in treating trophic ulcers.

Electrolysis is an efficient but very painful method of treating rebellious cases of pruritus, particularly pruritus of the anus or vulva, but can only be applied to small areas. The induced current from a powerful static electrical machine has been used for the same purpose and has the advantage of not being painful.

In using the induced current in other neuroses of the skin the author has had very inconstant results, sometimes finding either the nervous or the cutaneous phenomena relieved and the other one made worse; sometimes no effect on one or on both; sometimes both have been relieved and sometimes both have been made worse.

Internal treatment varies with the symptoms. Hygiene is very important, and frequently the trouble seems due to the abuse of alcohol, tobacco, carbon monoxide, and very often it will be found to be a symptom of gout, uterine, hepatic or kidney disease, etc., so that it is necessary to make a thorough general examination before excluding other troubles as the probable cause.

The author is pleased at the general recognition of his statement made fourteen years ago, that "the skin ought, in most cases, to be considered the mirror of the nervous system."

IN THE BUFFALO MEDICAL AND SURGICAL JOURNAL

Dr. Frank J. Thornbury writes of the

Pathology of Trichinosis.

The disease occurs epidemically in herds of swine, the old animals being particularly liable to the disease, and the diaphragm, neck and loins being favorite sites for the parasites.

As many as eight trichinæ have been found in one capsule, but frequently they are separate.

In a few recently affected subjects the parasites were found, not yet encapsulated, in motion, and this motion was increased by the application of heat.

When too few trichinæ to cause death are swallowed they bore into the muscles of the most remote parts of the body, and as 14 per cent. of the bodies examined in the Buffalo dissecting-room proved infected, the author thinks that a great many of the cases

of obstinate chronic rheumatism are due to infection with this parasite.

HARPER'S MAGAZINE.

Senator Henry Cabot Lodge contributes to *Harper's Magazine* for January a vigorous article, entitled "Shakespeare's Americanisms," which contains reassuring and comforting doctrine for those who employ colloquial forms of speech. The following passage is one of many that will be read with interest: "Among characteristic American words none is more so than 'to guess' in the sense of 'to think.' . . . One sees it continually in English comic papers and in books also, put into the mouths of Americans as a discreditable but unmistakable badge of nationality. Shakespeare uses the word constantly, generally in the stricter and narrower sense, where it implies conjecture. Yet he also uses it in the broader American sense of thinking. For example, in 'Measure for Measure' (act iv, scene 4), Angelo says, 'And why meet him at the gates and redeliver our authorities there?' To which Escalus replies in a most emphatically American fashion, 'I guess not'"

HARPER'S WEEKLY.

Probably no other paper has more largely influenced public opinion in America, through the views that have been expressed and the reforms that have been advocated in its editorial columns, than has *Harper's Weekly* during the thirty-eight years of its existence, and its recent political articles and signed and unsigned editorials have been conspicuous for ability and for constructive as well as destructive criticism.

HARPER'S BAZAR.

Volume xxviii of *Harper's Bazar* will open brilliantly in January with the beginning of Maarten Maarten's striking and finely illustrated novel, "My Lady Nobody," a story which has Holland for its background and some charmingly real people for its *dramatis personæ*. Marion Harland will contribute a characteristic short story entitled "A Fin de Siecle Prodigal," and Harriet Prescott Spofford a piquant tale, with a whimsical New England heroine. Other features will be a paper on "House Building," from the woman's point of view, by Helen Evertson Smith, and the first of a series on "Colonial Dames," by Catherine T. R. Mathews. The fashions for January will embrace elegant toilettes for occasions of ceremony by Sandoz and Chapuis, from Worth models, and many beautiful outdoor costumes.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE

On the Treatment of Tapeworm.

Leslie Ogilvie, M.B., refers (*Lancet*) to the frequency with which the parasite is treated with success, as evidenced by the reappearance of the proglottides in the evacuations after the lapse of three or four months. He thinks it is not a question of the particular drug to be used, but the method of using it, and considers the directions as ordinarily given in text-books very defective. As an antecedent purgative he prefers sulphate of magnesium with jalap, which he repeats several times before he administers the vermifuge. The latter is given in two doses, of a dram each, at intervals of an hour. Two hours after the last dose he clears out the bowels again with a dose of castor oil and tincture of jalap. In this way he thinks he secures the most powerful effect on the worm with the least effect on the patient. He claims to have been successful in the complete removal of the parasite in thirteen consecutive cases. He considers it of importance to prepare the patient for a few days previously by dieting, and recommends the physician always to pay a visit to the patient shortly after the second dose of the vermifuge, and to inspect himself all the evacuations, which for convenience he directs to be passed into a weak solution of potassium permanganate.

The Etiology of Headache.

Dr. S. Vermel (*Revue Gen. de Clin. et de Ther.*), after a thorough study of the subject, says that he is inclined to attribute all headaches to an oversensitive condition of the sympathetic nerves controlling the peripheral vessels of the cranium and brain, or to an angioneurosis. It may be asked at once, he says, how the same symptoms, from the same cause, can be present in diametrically opposed conditions, such as plethora and anæmia, febrile and apyretic diseases, for example. The idea that the seat of pain is in the cortex has not been substantiated, for when a cortex is irritated there is locally only an hallucination of pain; the real pain is exhibited on some part of the body. Then if the attack of cephalalgia is not due to local irritation of the cortex, the seat of the trouble must be in the meninges. It is to dilatation of the vessels of the meninges, causing intracranial pressure, that the pain is due. The vascular dilatation extends to the minute blood-vessels in the region of the pituitary body, rupture of which gives rise to the epistaxis from which patients so frequently suffer during an attack of headache. It is

clear how this explanation answers for hyperæmic conditions, but how does it account for the same symptoms in anæmia? In anæmia there is a qualitative and not a quantitative change in the blood, the amount of fluid in the vessels remaining the same. In veritable anæmia from excessive depletion of the system, as from hemorrhage or cholera, the condition is different; but from the anæmia coincident with neurasthenia, hysteria chlorosis, etc., there is, so far as quantity is concerned, the same condition as hyperæmia.

In anæmia the vessels are very prone to dilatation, producing an exaggeration of the intracranial pressure, in consequence of over-excitability of the vasomotor centers allowing of local hyperæmias.

The author definitely states that the seat of pain in headache is always in the dura mater and not in the cortex; that the pain is provoked by the compression of the dura mater produced by increased intracranial pressure; and that this is true of all headaches, whether neuroses or of toxic or mechanical origin—such as diseases of the brain or of the meninges, constipation, etc., or of reflex origin.

PATHOLOGY.

Experiments on the Inoculability of Cancer.

Dr. Gratia, at the meeting of the Paris Academy of Medicine, said: In connection with Dr. Lienaux, *agrege* at the State Veterinary School, I have carried out a series of experiments in order to throw light, if possible, on the moot question of the inoculability of cancer. We have made use of both grafting and inoculation. We grafted fresh cancers on the skin, the peritoneum and the wall of the stomach; in all but one case we obtained immediate union. For inoculations we employed fresh cancer juice obtained by scraping or rubbing primary and secondary tumors. This juice, either pure or diluted with sterilized broth, was injected in doses varying from one-fourth to one-half cubic centimeter or more, choosing by preference for such inoculation those organs which are most frequently attacked by cancer. The results of our endeavors to transmit cancer from dog to dog or from man to dog were invariably negative, both with regard to grafting and inoculation.

The conclusions at which we have arrived from our personal researches are that under similar conditions cancer does not appear to be inoculable, even between individuals of the same species.

Taking into account all the facts actually known, we think the following deductions are justified:

1. The parasitic nature of cancer has not been satisfactorily proved.

2. The direct or indirect contagiousness of this neoplasm has not been proved, the most that can be admitted, in the present state of our knowledge on this subject, being the possibility of ingrafting, that is to say, transplanting cancer, and that principally on individuals exhibiting exceptional predisposition, such as cancerous patients themselves, for instance.

3. The etiology and pathogeny of cancer are still undetermined.

OBSTETRICS.

The Conduct of Ordinary Labor Through External Examinations Solely.

Drs. Leopold and Sporlin (*Med. News*) make a warm plea for limiting examinations made in the course of ordinary labor to the external parts, and adduce the advantages of such a course. Infection is thereby avoided, the natural sense of modesty of the parturient is not offended, and careless rupture of the membranes is avoided. Skill in external examination is acquired with reasonable readiness. In the large majority of cases such examination alone is sufficient for the recognition of the position and presentation of the fetus and for the study of the course of an ordinary labor. As there can be no objection to its frequent exercise, abnormalities of parturition may the more readily be detected early and means of correction be promptly employed. Experience soon teaches the difference in the position of the fetus assumed in case of pelvic contraction on the part of the mother. The position and presentation having been recognized by external examination, internal examination for the determination of possible pathologic conditions of the birth canal need be but brief, and can be conducted with great care. For the attainment of this desirable result it is essential that the obstetric pupil familiarize himself thoroughly with the conditions of normal labor as determined by physical external examinations, as well as with the physiology of normal labor. Obstetric operations are principally to be taught upon the phantom.

SKIN DISEASES.

The Treatment of Eczema.

Malcolm Morris, in a paper read before the Dermatological Section of the British Medical Association, treats on the management of eczema. With regard to internal medication, the less the better. In an ordinary chronic eczema, when the health does not appear to be affected, he relies entirely on local treatment. In acute inflammatory lesions antimony is of great value, beginning with ten to fifteen minims of the wine of antimony and repeating the dose in an hour, and if need be two hours later, then gradually reducing to six minims three times in twenty-four hours. With regard to local treatment, he treats every case as if it were of parasitic origin. The best remedy in dry chronic eczema, especially of seborrhœic origin, is sulphur, and next to that resorcin. He begins with ten grains of precipitated sulphur or of resorcin in an ounce

of zinc ointment, gradually increasing the amount of parasiticide. When the inflammation is acute ichthyol is especially useful. When there is much discharge he washes the part with a weak solution of boracic acid, and afterward dries it with muslin bags containing starch and boracic acid or flour mixed with boracic acid. Chrysarobin has been successful with very persistent chronic eczema of the flexures.—*Boston Med. and Surg. Jour.*

DISEASES OF THE EAR.

The Necessity of Protecting the Ear in Bathing.

Bathing without properly protecting the ears will not infrequently bring about an otitis media, and also other affections of the ear have been attributed to it, and as these affections can be prevented by very simple devices the attention of the public should be drawn to the matter. Dr. Laurence Turnbull, of Philadelphia, has drawn attention to the fact that if the water which has entered the ears in bathing is not removed (which can be done by leaning the head on one side and drawing the external ear forcibly outward, at the same time shaking the head and opening the mouth, also striking the ear with the palm of the hand) inflammation, followed by perforation of the membrana tympani, may occur in consequence of the decomposition of the water. Or the suppurative process may pass to the middle ear, cochlea and labyrinth, destroying the organ of hearing and even implicating the brain. A large number of diseases of the ear are attributed to sea-bathing, that is, bathing too frequently and remaining too long in the water. Exostosis of the meatus is particularly common in persons that indulge in the "header." The ears, especially if they are tender or diseased, should always be protected in bathing. Dr. Turnbull advises that ladies should wear an oilskin cap covering the ears and men should close the external meatus with a piece of cotton or other simple plug, which may be removed after leaving the water. This precaution is particularly advisable for surf-bathing and when floating on the back.—*Med. Review.*

NOSE AND THROAT.

The Asthmatic Nose.

The exaggerated ideas of the importance of nasal reflexes, as formerly held by many specialists, have led the more conservative general practitioner to doubt the existence of any relation between the nose and any pronounced disturbance of function in other parts of the body. The part played by the nose in the various forms of asthma has been so clearly demonstrated by some of our ablest authors that no reasonable excuse can now be given for neglecting a careful examination in these cases.

Many theories have been advanced as to how the disturbance is produced, and as to just what pathological condition in the nose is necessary to produce it.

Where there is sufficient hypertrophied tissue to produce pressure upon the septum, or, on the other hand, where the septum deviates sufficiently to impinge upon the turbinates, we are most likely to have some reflex disturbance which may manifest itself in an attack of asthma or an irritability of the larynx. That there are other causes for asthma it is impossible to deny, but that there always exists a certain well-defined relation between nasal diseases and what is commonly called hay fever is just as certain. From the experience we have had with these we are inclined to believe that the middle turbinate is the *sine qua non* in the production of this disease. In all cases we have seen there has been marked disturbance in the region of this body, with pressure caused either by hypertrophied tissue or enlargement of the bone. Just how this pressure causes a disturbance in the respiratory function, and why it should be perennial in its occurrence, are questions of much uncertainty. Pollen of the different autumn plants and dust are regarded as very doubtful factors in bringing on the attack by some of our most eminent observers. The peculiarity of a regular occurrence at almost exactly the same time each year suggests the probability of some mental influence. However this may be, a slight operation in the nose previous to the expected attack often delays or entirely prevents its occurrence.

Where polypi or other growths exist their removal often results in permanent benefit. The success which has attended careful nasal treatment in asthmatic cases seems at least to promise a better understanding and a more scientific management of such cases.

During an attack of hay fever, frequently repeated and prolonged douching with hot water gives most satisfactory relief. The œdema seems to disappear and then follows a most agreeable sense of comfort. Cocaine produces temporary relief, but the secondary effect is really to increase the œdema Weak solutions of atropine sprayed into the nose will often relieve local symptoms. Local treatment alone is not usually sufficient in these cases. Some attention must be given to the general condition of the patient. The syr. hydriodic acid has been highly recommended, and we have found it very satisfactory in these cases. Strychnia in one-thirtieth-grain doses is also a valuable adjunct to local treatment.—*Kansas Med. Jour.*

HYGIENE.

The Clothing of Infants and Children.

The following sensible directions are given for the dressing of the child at birth by Dr. T. W. Peers in the Kansas *Medical Journal:*

1. A square of absorbent cotton five to six inches square, with a hole in the middle, is adjusted smoothly round the umbilical cord and the latter turned up toward the chin and covered with a second piece of absorbent cotton without a hole.

2. A soft flannel band around the child's body which will reach from the nipples to the crest of the ilium, and pin it in front with small safety pins.

3. A diaper of soft cotton or cotton flannel; not unwashed, harsh new goods.

4. A soft flannel gown, made with sleeves, but no waist, and about one yard in length, open the full length in front and tied with tapes or buttoned.

5. A dress of silk, tennis flannel, figured woolen goods or unstarched linen, according to the weather, fancy or purse of the mother, made similar to the above gown or with a waist if preferred, a few inches longer and with larger sleeves.

When the cord has come off and the stump thoroughly healed the flannel band should be left off. At five to eight months, when the baby gets to kicking and short clothes are indicated, the following dress is suggested:

1. A flannel shirt reaching to or below the pubes.

2. Diapers.

3. Woolen stockings reaching well up above the knees.

4. Shoes with a wide, strong sole and plenty of toe room.

5. A well-fitting waist of cotton goods, to which is attached the garters and a flannel skirt. Ring garters should be avoided.

6. Later, when the child learns to attend to the calls of nature, the union garment, which includes shirt and drawers woven in one piece, is a very desirable article of clothing.

Bicycle Exercise for Women.

Dr. Laura Liebhardt states (*Woman's Med. Jour.*), regarding bicycle exercise for women, that "the majority ride with the saddle too low," and that this is responsible for cramping of the chest, straining the back and impeding full action of the muscles of the leg. There results a constant tension of the muscles above the knee, which gives a short, awkward stroke, as the reach is too short. The seat should be amply high for the entire leg to be extended and give to these muscles a second of relaxation on the downward stroke of the pedal. The knee must have perfect freedom, and in this respect a woman finds herself particularly handicapped, as she is unable to make the entire stroke with the action of the knee limited by a dress skirt. In Paris they do not stop with the unsightly bloomers, but have almost universally adopted the practical, yet far too radical, knickerbockers. This striking costume attracts but a passing notice, for the rationale of it all appeals to the French mind; but as the United States has fortunately not yet reached the Parisian standard, it is to be hoped that knickerbockers will confine themselves to spins in the mountains. Wheelwomen also subject themselves to needless jars by jumping instead of gliding from the wheel. They should be taught to mount and dismount from either side as men are wont to do. Corsets on the wheel, as elsewhere, should be denounced in the strongest terms, although nearly one-half of all wheelwomen tie up their muscles in this barbaric fashion. Many condemn cycling on the ground that the movements are identical with those called forth in running a sewing-machine. Machine-running simulates more the faulty way of wheeling, and the position is almost identical with that assumed when the handle bars and saddle are placed too low. In wheeling there are a greater variety of movements and less tension. Two-thirds of all women who ride wheels foolishly incur great risks by riding during certain periods, even to the extent of hill-climbing, when they should never mount a wheel, except for short distances, during the first two days. During the Nebraska discussion the general opinion was that the saddles in use were hardly proper. The long, wide saddle suspended between springs was considered very much superior to the rigid or hard models. A saddle much wider throughout was considered desirable, and cases were quoted to substantiate this claim.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM DECEMBER 23, 1894, TO JANUARY 5, 1895.

The order assigning Captain James D. Glennan, Assistant Surgeon, to duty at Fort Snelling, Minnesota, is revoked. The order assigning First Lieutenant Henry A. Shaw, Assistant Surgeon, to duty at Fort Niobrara, Nebraska, upon the abandonment of Fort McKinney, Wyoming, is so amended as to direct him to report for temporary duty at Camp Merritt, Montana, and upon the completion thereof to proceed to Fort Snelling, Minnesota, for duty at that post.

Leave of absence for one month on surgeon's certificate of disability, with permission to leave the limits of the Department, is granted First Lieutenant James M. Kennedy, Assistant Surgeon.

Leave of absence for one month, to take effect about December 24, 1894, is granted Major Robert H. White, Surgeon.

The leave of absence on surgeon's certificate of disability granted Major Washington Matthews, Surgeon, is extended four months on surgeon's certificate of disability.

SKIN-GRAFTING—PSEUDARTHROSIS OF LEG—FAULTY UNION OF DOUBLE FRACTURE OF FEMUR.*

ROSWELL PARK, A.M., M.D., Buffalo, N. Y.

This is a case of skin-grafting which you saw a week ago and which I promised you should be brought into clinic to-day. Apparently every graft has united. You can estimate the saving of time which such an operation affords. I will irrigate the leg with a stream of very little force, so as not to wash off any bits of skin that have not completely united, and any pyoid material too tenacious to be removed by irrigation will not be disturbed. I want you to notice that the tip of the irrigator when not in use is kept in a glass bucket of sublimate solution. The wound is dusted with iodoform and covered with green silk protective. Half the secret of success in surgical work is the attention given to the dressings after the operation, and there is many a junior practitioner who can do an operation well, but who is at a loss what to do when the after treatment is considered. Therefore I like to do dressings before the class in order that they may become familiar with this less showy but important part of surgical technique. Two days is about as long as a dressing of this kind should remain in place, as the pyoid material will collect under the protective and it needs to be washed away, as it is prone to putrefy. Bichlorid gauze is applied over the protective to bar out germs of decomposition and the limb is bound to a splint to insure perfect rest. This I believe to be an important factor of success. The leg might have thrashed around in coming out of the anæsthetic so as to have displaced the grafts. At present the prospect is very good, but I have seen cases that showed the same amount of progress at this time that failed because the operator was satisfied with the result and became careless with the later dressings. The case must be watched with extreme care for at least a week longer.

*A clinical lecture at the Buffalo General Hospital.

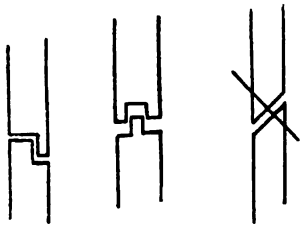
PSEUDARTHROSIS OF LEG.

This patient is a man of forty-five who has had a series of accidents involving the right leg. Thirteen years ago he broke it for the first time and it has been twice broken since. Part of the time he has had a good, useful leg and part of the time an ununited fracture has interfered with walking. At present there is a pseudarthrosis or flail-joint from a fibrous union of the bone. He is able to bear his weight on the leg, but it warps under him and gives him a very shambling, awkward gait. The deformity is gradually getting worse. There is now a concavity

amounting to a quarter of a circumference from ankle to knee. There is already shortening, and I have told the patient that although operation will probably relieve the instability of the limb, it will not obviate the shortening.

This is not merely a case of delayed union in which it suffices to stimulate ossification by rubbing the bone-ends together or by drilling. Here are bone-ends whose osseous tissue has been replaced by fibrous tissue, which acts as a tough leather thong to keep the bone-ends from wandering too widely from each other, and no result is to be looked for unless one opens up the region freely, cuts away the fibrous tissue, denudes the ends of the bones and brings the freshly cut or sawed surfaces together.

Just how the bone-ends may be best held together is a question to be decided during the operation. Sometimes we use mechanical devices. For instance, we may saw the ends obliquely and hold them to-



gether with a drill; or one may mortise or dove-tail the ends of the bone together. The principle is the same, although the details must be adapted to each particular case.

Before the application of the Esmarch bandage in order to make a practically bloodless operation, the leg is scrubbed, shaved and disinfected. Hands, dressings, instruments—everything that comes in contact with the wound must be completely sterilized. This leg was all scrubbed and cleaned yesterday, and an antiseptic poultice of green soap containing 5 per cent. of hydronaphthol has been kept on it ever since. Yet we shall apparently waste time by repeating the process to-day. So thorough is the scrubbing that it would be positively painful were the patient not anæsthetized.

Nearly half-way up the leg there is a large, roundish knob of bone. Eight or nine years ago an operation was performed for false-joint, which was successful, but the leg was again broken at a lower level. I will go a little to the inner side of the old wound. There is a little gelatinous fluid that oozes out of the false-joint cavity. This shows that we have really to deal with a newly formed joint.

It has been suggested to use a depilatory instead of a razor in preparing the field of operation. Calcium hydrosulphate has been generally used for this purpose. It is spread on for a few minutes and then washed off with water, taking the hair with it.

The relations of the parts here are so distorted that one hardly knows where to look for vessels and nerves. Now, if the bone were a piece of wood we could take it out, put it in a vise and saw it to any desired shape, but in its surroundings it is very difficult to form an idea of the exact outline required, and the task of the surgeon, so clearly indicated theoretically, is very difficult in practice. I contemplate making an oblique section of the bone with a chisel, since I cannot get in with a saw. Bichlorid gauze is crowded about the bone so as to prevent chips from getting into the wound.

It is very interesting from a morphological standpoint to note that so perfect has been the development of a joint in this case, that in addition to the fibrous covering of the bones, the semblance of ligaments and the synovial fluid, we even have an intra-articular fibro-cartilage. From the surgical standpoint, however, this interesting development delays the operation and makes it mechanically more difficult. The cutting of the bones is further delayed by the fact that they are almost as hard as iron. It is a strange and yet commonly observed fact that in the neighborhood of softening bone, or failure of bony development, we are quite apt to have excessively hard bone. The fibula is adherent to the tibia and must be separated so as to restore the normal contour of the limb.

I have now succeeded in removing the dense fibrous tissue and in freshening the bone ends. Now, while firm traction is made on the foot I will drill the bones with the aid of a dental engine. Through the drill holes silver wire is inserted, twisted together over the bone, and the twisted end laid flat so that it may become encapsulated without subsequent annoyance to the patient. The flesh-wound is

closed with catgut and dressed antiseptically, without drainage.

FAULTY UNION OF DOUBLE FRACTURE OF FEMUR.

This patient is a little child of three whose left femur was broken six weeks ago. From the appearance of the thigh it is evident that it was broken in two places, so as to leave a loose fragment in the middle. There is both angular deformity and over-riding of the fragments, and the limb is two inches shorter than its fellow. It would be a pity to let the child grow up with such a deformity. It is a question, however, whether we would better resort to osteoclasis or make a free incision down to the bone and chisel apart the faultily united fragments. The case is, in one sense, the opposite of the last one, yet the end of the operation is the same, namely, to secure the fragments of bone in their normal position. Theoretically I would much rather do the external operation, for it obviates the possibility of the entrance of septic germs through a wound. On the other hand, the ends of the bones are wrapped up in more or less callus, and I do not think that by breaking the bone in my hands or by bringing an instrument to bear upon the thigh I can free the fragments from the callus so as to get them into good apposition. I purpose, therefore, cutting down upon the bone under the most rigid asepsis, for there is no class of surgical work in which primary union depends so closely on the strictest exclusion of bacteria. Oliver Wendell Holmes describes a class of people who go around washing their hands in invisible water with imperceptible soap. I want you to notice that in my case the lather is tangible and real, and that I am working the green soap under the nails and into every crack of the skin.

The operation is a serious one for a child of this age. It is wholly different from breaking a rhachitic femur by the aid of a chisel passed through a small opening, as in Macewen's operation.

I can show you an example of over-riding of fragments of femur in a thigh bone taken from the old North Street burying-ground when it was being cut up into building lots. There must have been three inches shortening of the limb. Fortunately the doctor's name was buried with the specimen and it has not been resurrected.

The history of the present case, as I have just learned, is that the child fell on the floor and broke its thigh. I doubt whether that was the extent of the accident. If the bone would break in two places from such an injury we might diagnose osteomalacia, and certainly the bones should yield to manual pressure so that the serious operation, which I dread to perform on so young a child, might be obviated. The three parts of this femur form distinct, though very obtuse, angles. By external manipulation I have been able, somewhat to my surprise, to reduce the deformity very markedly. I will put on traction and leave the case for future operative interference if necessary. Although I have not restored the bone to an ideal straightness nor to the same length as the opposite one, I think it better to do this conservative operation on account of the large amount of callus, which would render the radical operation tedious, and also because the vitality of the bone is below par and necrosis might set in.

Let me call your attention to the best means of applying traction, and what I shall say will apply also to the treatment of recent fractures of the thigh in children. A little child will be restless and will inevitably soil its bed. Then the necessary disturbance to insure cleanliness and to prevent bed-sores will cause great pain if the leg is dressed horizontally, as it usually is in adults. But if the leg can be held vertical the weight of the child's body makes the counter-traction, and there is convenient access to the child's genitals and anus for purposes of cleanliness. If it is irksome for the child to have one leg held up in this way, both legs can be suspended.

Some time ago a boy was brought to the hospital who had been run over by a wagon and had sustained a simple fracture of one thigh and a compound fracture of the other. I operated upon him here, wired the femur which had suffered compound fracture and dressed the wound antiseptically. He was also bruised about the head and generally over the body; his vitality was impaired and recovery was necessarily slow. It was perfectly easy to care for the child with his legs trained up in the per-

pendicular direction. It would have been very difficult to have done so with the legs extended on the bed.

I apply a gauze bandage over the foot and ankle in order to keep the pressure of the adhesive plaster from the malleoli. The adhesive strip is then applied to the sides of the leg up as far as the lowest fracture and held firmly by the gauze bandage over it. You will probably want to know how much weight is to be fastened to the cord. This I cannot tell you offhand. It will be enough to keep the limb straight and not enough to exert any strain on the tender tissues of the child. Again, you will ask, Would it not be better to apply a splint to the femur to hold it straight? While splinting might be of advantage under some circumstances, it would make it impossible to examine the femur from time to time, and the main element of success in our treatment, as in success in other matters, is the *pull* which we can exert.

IMPORTANT QUESTIONS IN RAILWAY SURGERY.*

M. CAVANA, M.D., Oneida, N. Y.

Organization in railway surgery, as in other specialties, becomes valuable to its membership proportionately to the amount of its educational worth as the result alone of such organization. The average active railway surgeon, however busy his professional life, is generally willing to sustain the loss of time, the sacrifice of business and the monetary outlay necessary to enable him to attend the conventions of his surgical associations. But, not unlike other business men, he expects some return for his outlay, some compensation for his loss of time, something more than a short period of rest and recreation and the sight-seeing of an extended railway trip. He expects to gain that which to the truly loyal professional man is more than money, and which can only be purchased by a personal presence at such conventions, namely, such increase in his store of practical knowledge as will enable him to return the better qualified to his field of labor.

To render our conventions thus profitable to our membership and to insure a progressive and prosperous existence, we are of the opinion that, for the present at least, more attention must be devoted to those important and practical every-day questions of our specialty which as yet remain unsettled.

First and most frequently encountered is the question of the extent of the surgeon's liability and obligation to his employer (the railway corporation which he serves) in his connection with cases which are likely to result in claims for damages for injuries received or to become subjects for litigation when such demands are questioned or ignored.

It will be conceded the fact that the shrewd surgeon, possessing not only the confidence of his patient but also that of the friends, becomes a power in the sick-room and a very responsible factor in such a situation. Any suggestion from him will always be entertained, and his advice either to sue or to settle quite generally followed. Therefore, when requested by our claim agents, shall we as surgeons in charge of the injured encourage our patients to accept terms of settlement which of our own knowledge we know to be fair and liberal toward the patient and satisfactory and equitable to our corporations? Or shall we adhere strictly to our professional duties, ignore the interests of our employers in such cases, and permit, without even a protest on our part, the only possible conclusion of their drifting into the hands of unscrupulous attorneys?

Claims for damages resulting from railway injuries, like snow-drifts in the deep railway cuts, grow rapid with age and generally assume immense proportions in remarkably short spaces of time; particularly so following the exchange of the company's surgeons for the local pettifoggers who, the "streptococci" of railway enterprises, infest every locality and in-

* President's address, Fourth Annual Convention of the New York State Association of Railway Surgeons.

fect every approachable case of railway surgery, and who universally succeed either in forcing settlements at unjustly exorbitant figures (they pocketing the lion's portion of the amounts obtained) or in compelling on the part of the railway companies the defense of expensive suits at law.

In the future considerations of this question, the Chair recommends inviting the participation of some of our prominent railway managers or claim adjusters in addition to our own membership, in order that the conclusion obtained may be as nearly as possible the proper general guide in such situations.

The second important unsettled question is that of the cash value of human life, or the amount of liability in cases where death results from railway accident. This question is now governed by statute and the death liability fixed at $5,000. But the constitutional amendment (Article No. 18) adopted at our recent election repeals this law, thereby relegating this important question again to the unsettled column. Without questioning the wisdom of the adoption of this amendment or criticising the judgment of those who were instrumental in submitting the fate of the question to the unintelligent masses, we cannot deny that while the stages of life—infancy, childhood, youth, manhood and old age—vary materially in value, the repeal of this statute cannot but result disastrously to the railway corporations of the State, and that their interests demand our earliest possible consideration and solution of this question, and the establishing of a basis for intelligent and equitable calculation as to the cash value of life in its various stages of human existence.

Question third: Should railway surgeons procure from patients the histories of accidents and frame therefrom records of the material points bearing upon the causes and conditions surrounding such cases, and when possible over the signatures of the injured parties in the presence of witnesses? If so, would not much of the prevailing litigation be prevented, settlements of just claims be more easily effected, and unjust or fraudulent demands less often be prosecuted? For the solution of this question the Chair begs to suggest reference thereof to our able "alli" and coworker, the New York Medico-Legal Society, with a request for its consideration and for a recommendation to be presented at our next convention.

Question fourth: May not railway surgery become a potent factor in the suppression and detection of fraud? The principal suggestion prompted by this question is the great need of more liberal legislation bearing upon the rights of defendants in suits for damages. Parties seeking to recover for personal injury should be compelled by law to yield to the defendant, when properly requested, the privilege of a surgical examination of such alleged injury; and refusal on the part of the plaintiff to permit such examination should be evidence prejudicial to the security of the claim. Of course such privilege should be guarded by reasonable restrictions and necessary formalities, to insure good faith in the application therefor as well as in its acceptance. Verdicts of juries finding for the plaintiff (the usual termination of suits to recover for railway injuries) generally include liberal compensation for the probable continuation of the alleged disabilities for periods of time covering months, years, or even the remainder of the natural life, and the expensive features in the computation of such verdicts invariably are those of mental and bodily suffering, the loss of valuable time and the requirement of regular care, aid and attendance during the periods of total disability.

In consideration of the fact that a very large majority of the alleged sufferers from railway injuries, being quite securely protected by the existing faulty and incomplete statutes, very generally succeed in deceiving the courts and juries by assuming to suffer total disability during the trial of the causes, and by volumes of exaggerated testimony from unprincipled witnesses also frequently succeed in convincing such juries of the permanency of the apparent disability as well, what, then, is more argumentative of the necessity for better legislation than the proof of the occurrence of complete convalescence in a large number of cases, dating from the very moment of the settlement of their claims, and that no redress is by law afforded the unfortunate defendant who has paid a verdict covering the expense of a suffering life term requiring regular aid and attendance?

Additional legislation empowering defendants to compel surgical investigation in cases of premature convalescence, and to bring suit for the recovery of such portions of verdicts as may be discovered to have been obtained by deception and misrepresentation, and providing for the indictment of all the parties conspiring to sustain the frauds, would result in materially cheapening most of the claims for damages and in greatly lessening the number of railway cases upon the calendars of our courts. In such an event the unprincipled classes who now expend twice the necessary energy required to sustain life by honest industry in their diligent search for defects in the sidewalks and bridges of their localities and for railway complication upon which to base suits for damages, finding our laws punishing rather than inviting dishonesty and exposing rather than protecting fraud, would be driven from the field and their occupation practically ended; and the struggling corporations, supported by their surgeons, would then occupy positions equal and just with their plaintiffs in our courts of justice. Grant to our railway corporations the legal rights of enforcing subsequent surgical examinations and of reclaiming on verdicts proven unjust, then, in the judgment of the Chair, we will have discovered the most effectual eradicator and the most energetic prophylactic in the treatment of that notoriously obstinate and prevalent disability, the railway spine.

Shall we amputate or shall we wait? For a period of nearly two hundred years the subject of amputation has occupied the minds of the surgeons of the world, and from the beginning of the age of steam railways to the present time no one subject has grown more rapidly in importance nor is at the present day more frequently encountered by the railway surgeon. Associated with this is the astonishing fact that as yet no generally accepted criterion has been established as to what may be the safest and most favorable time for amputation. Abundant evidence and eminent authority may be cited in support of either immediate or delayed interference in cases of crush injuries, and in consequence the conservative surgeon discovers little satisfaction in consulting his text-books or authorities upon the question.

The legal complications so liable to result from the present unsettled conditions of our practice and literature upon this subject, are such as threaten to involve the operator in a large percentage of his cases, and suits for malpractice and for the recovery for damages have so frequently followed amputations that to-day few of our leading surgeons dare even to hold recorded titles to real property. In support of these arguments permit us to submit an example illustrating present possibilities.

A New York State surgeon accepts the care of a case suffering from a crush injury of an extremity. He is untiring in his professional attentions to the patient, exercises therein his best possible judgment supported by a liberal consultation and careful following of some of the acknowledged authorities. The patient encounters certain of the unfortunate liabilities and eventually succumbs.

In the malpractice suit which follows an expert surgical witness testifies that in his judgment and belief the amputation should have been deferred to a much later period or until the line of demarcation had appeared.

The next witness testifies that the amputation should have been immediate, or as early as the establishment of reaction following the injury. He also submits rational argument and abundant statistics in support of his assertion.

The third witness expresses the opinion that it would have been much safer practice to have accepted an intermediate period for the amputation. He argues that such interference should be delayed until the patient has been afforded ample time for complete reaction and preparation for the ordeal.

Expert witness No. 4 expresses as his opinion, founded upon a careful review of all material facts in the case and upon his own wide experience with traumatisms, that amputation at any period was inadvisable and uncalled for in the case. He substantiates his assertion by illustrative proofs of recoveries of cases wherein much more extensive destruction of tissue ensued, and which recoveries resulted in a very satisfactory degree of usefulness of the injured parts.

In framing of verdicts in modern medical cases by the illiterate elements composing the usual petit juries, can we wonder that in their attempt to weigh the

medical and surgical evidence the poor creatures in despair are forced to the silent query, "Where are we at?"

The signs of the times point to the State organizations as the coming educators of railway surgery. They are much more wieldy, their conventions more accessible and their membership much less changeable than are those of larger bodies. Therefore we feel privileged to urge upon this association the arming for the fray and equipping for that untiring action that will result in such continuous agitations of our present important unsettled questions as will enable us to establish authoritative precedents for the general guidance of the surgeon in his conduct upon the witness-stand as well as in the care of the patient.

The interests of our corporations, the welfare of our patients and our own individual safety demand early conclusions in these questions, especially of amputations. For this reason the programme arranged for the day's deliberations bears evidence of the initiatory step toward the coveted results.

The jurisdiction of our organization includes territory richer in resources and more prolific in means for demonstration and experiment than any other State or commonwealth of the continent. The names appearing upon our membership rolls and those upon the day's programme are sufficient guarantees to the most incredulous of New York State's ability to cope with the task which we urge upon her.

Then may we hope that our future conventions will continue to make satisfactory progress toward the ultimate solutions of the now important unsettled questions in railway surgery.

THE CLINICAL THERMOMETER.

J. W. CARHART, M.D., La Grange, Texas.

The intelligent practice of medicine at the present time implies a reasonable proficiency in the subject both as a science and as an art.

Every qualified physician should congratulate himself that medicine has, to a great extent, rid itself of the mythical—has dropped the shadowy veil that for centuries obscured its beauty; and that now, as never before, its power and grandeur are the admiration of the world.

The speculative has become subordinate to the demonstrated, so that what cannot be proven is not to be received and incorporated into our medical creed as an article of faith and practice. We undertake to carry out the injunction, "Prove all things; hold fast to that which is good." The widespread spirit of deep and thorough investigation and original research which is fully satisfied with nothing short of demonstration has laid under contribution every instrument of precision that can be advantageously employed in the work of the learned practitioner in the alleviation of human suffering. This spirit of investigation and research is not satisfied with instruments provided ready to hand, but has taxed to the utmost the masterful inventive genius of the age, and has originated vast numbers of appliances of incalculable value, which the astonished intelligence of this brilliant period stamps as curious, useful and now indispensable.

The microscope has furnished us a revelation of the minute atoms of the field of histology. Physiological chemistry handed us the test-tube, while physics gave us the spectroscope. Not content with these we asked for the sphygmograph and the spirometer; and that our armamentarium might be more complete, we asked of science and of art a thermometer that would register the tenth of a degree of thermal change in the human system, and the contribution was at once made.

So thoroughly accurate has enterprise made these instruments by years of seasoning and the application of the severest tests that my Taylor Brothers' thermometer has never failed to register the slightest variation, even to the tenth of a degree.

So far from having exhausted resources, we are convinced that the work in the demonstrative department of our profession is but begun and that we are on the

borders of a vast field which we shall enter and widely explore.

While we contemplate with just pride the solid advances by our profession in the work of demonstration and in the production and use of instruments of precision, we feel constrained on this occasion to sound a note or two of warning lest, in our use of such instruments as the clinical thermometer and the sphygmograph, we come to depend upon them instead of using them as accessories, and thus lose the *tactus eruditus* of which the fathers of medicine made such ample use and without which, I undertake to say, no man or woman can practice medicine with either safety or success.

I have chosen this subject in order that I might call your attention to what I regard as a startling defect developing in many of the younger members of the medical profession, and which promises to increase and to become more pronounced, growing out of the abuse of the clinical thermometer. I refer to the present lack of that habit and consequent deficiency of skill which was possessed by the better class of practitioners in the examination of the pulse and the determination of temperature, or rather of thermal changes, by the educated touch before the introduction of the clinical thermometer. The modern sewing-machine, with its marvelous capacities, is a monument of our civilization; but it can never wholly usurp the place of the delicate needle in the deft fingers of an intelligent woman. Our appreciation of lithographs, however beautiful they may be, can never equal the admiration we feel when viewing the sublime paintings which are the monumental products of the immortal masters. Thus, though the clinical thermometer is of incalculable value, it neither can nor should it ever take the place of the trained fingertips. Wherever it does supplant the latter, the patient suffers and our profession receives a stab.

The sphygmograph cannot interpret or transfer all the qualities of the pulse, any more than it can convey a distinct idea of the heart-sounds. That requires the practical ear. Nor can the clinical thermometer do more than register the thermal condition of the patient. The temperature chart, with all its graceful curves and geometric lines and angles, may please the vanity of the devotee of instruments of precision, while, undetected by the skilled touch, the depressed heart may suddenly "cease at once to work and live."

This danger is increased by the antipyretics so extensively in use during the last few years. The doctor, stimulated by the wish of patient and friends, pushes the antipyretics, noting with satisfaction the temperature chart, without in too many instances ever touching the wrist to study the pulse, until, to the amazement of the doctor and the consternation and grief of friends, the patient is dead. "Heart failure" has come to be the hackneyed and unmeaning registration as the cause of death—unmeaning, except as it betrays the ill-advised dependence upon that little instrument of precision, the clinical thermometer.

The shocking mortality in typhoid fever may be justly chargeable, to a great extent, to the clinical thermometer. For several years I have not used a clinical thermometer in typhoid-fever cases. I administer antipyretics with the most sparing hand, endeavoring to conserve the heart's integrity which is so liable to be impaired in this disease. There is no difficulty in determining without a thermometer the thermal changes, at least with sufficient accuracy, extraordinaries excepted, for practical purposes in typhoid fever, and for that matter in almost any other fever.

If we allow one degree of temperature over 98.5° for every ten beats of the radial pulse over 75 to the minute, we can determine the temperature even to the fraction of a degree. With the trained fingers upon the pulse and the trained ear over the heart, we cannot well be misled either as to temperature or as to the condition of the suffering heart.

Some practitioners of medicine are liberally endowed with the faculty of observation which they have diligently cultivated and largely developed, while others are seemingly lacking in this most essential qualification of a good physician. No instruments of precision can compensate fully for the lack of this admirable power. The less we depend upon the clinical thermometer and the more we come to regard it as merely auxiliary to the educated touch and to careful, thorough scientific observation, the better it will be for all concerned.

In the matter of observation there must

be taken into account all the considerations, surroundings and circumstances of the patient. This the sphygmograph and thermometer cannot do. For example: "The frequency of the pulse is increased by the activity of the working organs, by muscular labor, by digestion (increased glandular labor), by psychical processes (emotions, pain, intellectual labor), exposure to heat and elevation of the body temperature. Position, in accordance with the muscular labor involved, affects the pulse-rate, which is higher standing than sitting, higher sitting than lying. Guy found the averages in adult males standing, 79; sitting, 70; lying, 67; with remote extremes and the differences increasing with the frequency of the pulse. The differences are less marked in females and in early youth. Graves states that in hypertrophy of the heart these differences disappear, and the same has been said of pregnancy."*

There are likewise conditions affecting temperature which are not taken into account if the object be simply to reduce the temperature as shown in the reading of the thermometer. What might be regarded as high temperature under one set of circumstances would not be regarded as such under different circumstances.

We insist, therefore, that while the clinical thermometer is a useful instrument in the hands of the observing physician, it may be an instrument of death with the unobserving who simply seek by antipyretics to reduce fever.

GOLD AS A THERAPEUTIC AGENT.

W. H. WALLING, M.D., PHILADELPHIA.

Gold has long been used as a remedial agent, but to a very limited extent. This was due probably to the fact that but one preparation, the chloride, was available.

Within a few years, comparatively, the bromide of gold has been added to the list of preparations. Still more recently the tribromide has been presented by an experienced chemist, clinical results proving its great superiority over the other preparations. Gobert states that the bromide of gold and sodium is far more prompt in action and much more certain than are the other bromides, the doses at the same time being far less in amount. He considers $\frac{1}{10}$ gr. of the bromide of gold equivalent to ten to thirty grains of the bromide of potassium or sodium in the effect upon epilepsy.

Fèrrè, of Paris, studied the relative toxicity upon animals of the bromides, and tabulated them in the following order: Bromide of mercury, bromide of cadmium, bromide of gold, bromide of barium, bromide of copper, bromide of manganese, bromide of zinc, bromide of arsenic, bromide of potassium, bromide of nickel, protobromide of iron, bromide of magnesium, bromide of ammonium, bromide of calcium, bromide of strontium, bromide of lithium and bromide of sodium.

The solutions used were of the strength of 1 per cent., and of this ten c.cm. (two and one-half drams) were injected intravenously every minute.

Shteherbak found that gold bromide was six times as strong as the bromide of potassium in its action upon the psychomotor centers, although it contains only 55 per cent. of bromine to 77.7 per cent. of bromine in the potassium salt, and 67.2 per cent. in the bromide of sodium.

Later writers have had most gratifying results from the use of the bromide of gold in a variety of diseases, notably in the scleroses. Combined, however, with arsenic, it seems to exert its most pronounced effects.

The preparation which I have used with great benefit in locomotor ataxia and kindred affections is a solution of the tribomide of gold and the oxybromide of arsenic.

This solution is of a beautiful magenta color, perfectly transparent and is permanent. The coloration is due entirely to

* "Wood's Reference Hand-Book of the Medical Sciences," vol. vi, p. 85.

the tribromide of gold, the other bromides being colorless. Each ten drops from the dropping-bottle contains one-thirty-second of a grain of the tribromide of gold and one-thirty-second of a grain of the oxybromide of arsenic.

The utmost care must be exercised in the preparation of these delicate chemicals, glass and porcelain utensils only being used. They should not be allowed to come in contact with a metal at any time, either during the manufacture or in the dispensing.

Another combination that is very effective is the solution of the tribromide of gold and the oxybromides of arsenic and mercury containing the same quantity of each salt as the first solution named. The color is also the same.

This latter solution is a specific for all conditions arising from syphilis. It will produce salivation, but not in so marked a degree as other mercurials.

These solutions present the tri and the oxy bromides in the best possible form for administration; they are easily borne by the stomach, are prompt in effect and lasting. Goubert found that the bromide of gold completely controlled epilepsy; some cases going several years without a return of the complaint. Still better effects may be expected from the tribromide of gold and the oxybromide of arsenic. In several cases in which I have used this solution it has proved by far the most satisfactory of any medicinal remedy administered. It controls the fibrillary twitchings so prominent in some spinal affections, restores the tone of the nervous system, relieves melancholy and restores the failing energies of tired brain-workers. It also has a most marked effect upon rheumatism. One prominent physician writes me that since taking this remedy he has not suffered from rheumatism in the least, a relief that he has not experienced before in years. This preparation is also very effective in sciatica and other neuralgias.

The solution of the tribromide of gold and the oxybromide of arsenic in doses of seven to ten drops three times a day is very beneficial in sexual debility. One patient requested me to discontinue its use, as his "powers" became somewhat troublesome. The decided result in this case I attributed to the effect of the powerful alterative and tonic action of the chemicals upon the nervous centers, the lowered tone of which was the cause of impotence.

I have not used these preparations in inebriety, but from reports of the prompt effects from the administration of the bromide of gold in that neurosis, I am fully satisfied that still better effects would follow the use of the tribromide. In fact, this is a most valuable addition to our armamentarium for the treatment of all nervous diseases.

It is of the utmost importance that the tribromide should be carefully and properly prepared and dispensed only in solution.

Disappointment will result if these precautions are disregarded.

The Danger of Anæsthetizing Diabetics.

Baxer calls attention to the danger of narcotizing diabetics. He has reported three of his own cases and nine collected from medical literature. Even in slight cases of diabetes the patients became comatose and died. Coma did not develop until the chloroform narcosis had passed off, in twenty-four to forty-eight hours. The patients then became indifferent, stupid and confused, finally lost consciousness, urine and feces were passed involuntarily, and they perished in coma. This communication is important, since it shows that the administration of chloroform is dangerous even when there is a slight degree of diabetes, it being impossible to predict whether or not coma will develop.—*Deut. Med. Woch.*

Lactate of Strontium in Bright's Disease.

According to Dr. Ried (*Lancet*) the lactate of strontium, which is certainly an excellent diuretic, is beneficial in a large proportion of cases of Bright's disease, at all events when no sclerosis of the kidney has commenced. It should not be given in powder, as it is liable to provoke sickness; but when dissolved in the proportion of one to six parts of water, three or four tablespoonfuls can be taken per diem without unpleasant effects. Its diuretic action has induced Dr. Ried to believe that the lactate of strontium may be advantageously used instead of salicylates in the treatment of pleuritic effusions.

COMMUNICATIONS.

PRIORITY IN THE USE OF LATERAL TRACTION FOR THE RELIEF OF INTRA-ARTICULAR PRESSURE.*

A. M. PHELPS, M.D.,† NEW YORK CITY.

The question of priority always dates from the time of publication; only for this it would be possible for valuable discoveries to be appropriated by others. The question of an individual's statement in regard to a matter without the proof of publication is absolutely invalid for the purpose of establishing priority. This is only fair to investigators, and it is fortunate that the scientific world recognizes this fact, otherwise great injustice might be done.

As regards the question of the application of lateral traction in hip-joint disease for the relief of intra-articular pressure and fixation, and the manner of its application, I believe I was the first to publish it.

In February, 1889, I read a paper before the New York State Medical Society on "The Management of Hip-Joint Disease from an Anatomico Pathological Basis," which paper was published in the "Transactions" of the society for that year. It was also published in the New York *Medical Record*, May 4, 1889.

In that paper I published drawings of my lateral-traction fixation splints, and also a plaster-of-paris portable bed with lateral traction applied. I also explained the rule which should govern the application of extension or traction in hip-joint disease.

From that paper I quote, page 313, "Transactions," 1889:

"I fully agree with Sayre, Taylor, Barwell, Marsh and others that spasm of the muscles should be overcome by extension.

"I also fully agree with Thomas, of Liverpool, that every joint should be fixed and absolutely immobilized until all inflammatory action has subsided and a cure effected; but I do not believe that immobilization of the joint can be accomplished without extension, neither do I agree with the first-named gentleman, that extension immobilizes a joint sufficiently to get the best possible result, but that the combination of the principles of fixation and extension should be the law. Hence the long-traction splint, which admits of motion, does not immobilize, and the patient produces injury of the joint every time he steps upon it, as is evidenced in the vast majority of cases by the almost constant increase of the deformity after the splint is adjusted. Neither does a Thomas splint produce extension; hence there must be abnormal intra-articular pressure when spasm or contraction of muscles is present, which must produce congestion of the head of the bone. And then, if extension is to be applied, it should be in the line opposite to the line of traction made by the muscles; in other words, to apply extension to the hip joint, we should not only make traction in the line of deformity, but also in a line at right angles to that deformity. To relieve perfectly intra-articular pressure, extension must be made in a line corresponding to the axis of the neck, and not with the axis of the shaft of the bone, for the following reasons:

"The adductors and abductors pass from the femur diagonally across the body to the pelvis, as Figs. 1 and 2 'Transactions' will demonstrate. These, with other muscles, are the ones affected by spasm. When they contract, the head of the bone is grown firmly into the acetabulum, the force operating on a line corresponding to the axis of the neck. The flexors act on a line corresponding with the axis of the shaft."

Then follows a description of the plaster-of-paris portable bed with illustrations.

---

*Read before the American Orthopædic Association, May 30, 1894, Washington, D. C.

†President American Orthopædic Association, 1894.

"The manner of applying lateral traction while the patient is in bed, to overcome deformity, and also of the splints which I devised for the purpose of carrying out this idea, see pages 316–320 of the 'Transactions' of the same year."

So far as I have examined the literature upon this subject, this is the first paper printed that describes the application of the principle of lateral traction for the relief of intra-articular pressure and fixation in hip-joint disease. At the time I read this paper I was not aware that any one else had ever printed anything upon the subject, and I find, upon looking over medical literature, that no one else has published the fact of the application of lateral traction for the purposes indicated before my paper of 1889. I have had made a brief translation of what has ever been said upon this subject by the German surgeons.

"Med. Jahrbücher," 1873, Professor Albert, "Die Extension bei Coxitis:" "I was asked by Dumreicher to treat a large number of patients suffering from hip disease, and to treat them without extension, and afterward to compare the methods with those treated by extension. I do not like to establish a rule when I say that without extension we can get along at least as well, and perhaps better, than with the extension. If extension really removed the pressure of the corresponding inflamed bones, then it might accomplish something. It is doubtful if the inflammatory process is retarded or improved through extension. And then again I must say that every method of extension that constantly changes the position of the intra-articular surfaces is wrong. This is sure, that through the new method intra-articular pressure is not relieved, but, on the contrary, more intra-articular pressure is induced.

"Busch proves conclusively that extension does not relieve intra articular pressure, and rightly thinks that if extension is to be applied it should be in the axis of the trochanter and not in the shaft of the bone.

"He further thinks that the pressure is also a remedy, as it stops the growth of the inflamed vegetations."

He further says: "Professor Dumreicher has frequently said in his lectures that to relieve intra-articular pressure traction must be in two directions." But this was never applied nor published. He further says:

"I have seen cases where extension acted splendidly, when it was better than any other method, and if we were able to diagnose the pathological condition in the hip as we do in the knee I would not hesitate to apply it.

"Severe pain might be due to pressure between the articular surfaces, and if extension were to be used to relieve pressure it could only do so by being made in the axis of the trochanter."

Further reference: Busch, 1863, "Langenbeck's Archives," vol. iv, beginning page 50. Also vol. xiv, Czerny, *Wiener med. Wochenschrift*, 1869, No. 33 ff. Hüber, translated by Dr. Schepero.

So we see from this translation that lateral traction was not applied by either Albert, Busch, Dumreicher, or any other German. But they wrote in the strongest manner against any form of traction, and showed conclusively that if traction were to be applied it should be made in a line corresponding with the axis of the neck, and not with the shaft of the bone; but they make no mention of having applied it.

Wallace Blanchard, of Chicago, published an article in June, 1889, upon his apparatus for treating hip-joint disease, in which he attempts to make lateral traction. In his article he says: "It is beyond question that a really efficient apparatus for hip joint disease must meet three requirements:

"1. It must afford traction outward as well as downward, so that the mean force exerted shall be in an axis with the neck of the femur, and thus relieve from pressure all the articular surfaces of the joints.

"2. It must afford immobility.

"3. And allow of unlimited out-of-door exercise, as far as pain or danger to the diseased joint is concerned."

But this was published after my article read before the State Society in February, 1889. In this article are diagrams which are similar to ones which I have used in teaching for more than ten years.

Sayre, in "Sajous," 1890, vol. iii, gives Blanchard priority, and then he says: "We have done this for years with great satisfaction."

And then again in his article published in the New York *Medical Journal*, April 30, 1892, on "Results in Cases of Hip-Joint Disease Treated by the Portable

Traction Splint," he attempts to claim priority by publishing cases from his case-book.

It is needless for me to say that any statement made in the article of Sajous, or even in the article referred to, April 30, 1892, would be absolutely worthless to establish priority. And further, in this article of April 30, 1892, I find the following statement:

"There has been considerable discussion as to priority in the application of lateral traction in hip-joint disease. I may say that in looking over my notes I find I applied it to L. A. McC. in 1868, in the presence of Dr. L. M. Yale."

If this statement was true, even though it had never been published, I would be willing to give to Dr. Sayre due credit for priority. This case-book to which he alludes was presented at the Academy of Medicine to prove priority, and I have made a copy of the notes of the case. Now I find that Dr. Sayre did not in 1868 (according to his note book above mentioned) apply lateral traction to L. A. McC in 1868. The date is March 27, 1872. that he claims to have done it.

And then lateral traction for the purpose of relieving intra-articular pressure was not applied to L. A. McC. at any time, as this same note-book will prove: "A second weight was attached to the thigh by means of *adhesive plasters* in such manner as to cause *external rotation* of the limb." This was a case of hip-joint disease in the third stage, with extreme inward rotation, and the weights and pulleys were adjusted for the purpose of overcoming inward rotation and not for the purpose of relieving intra-articular pressure, as he claims. Then I think that the claim of Dr. Sayre to lateral traction is entirely invalid and will not bear examination.

In his discussion of a paper which I read upon this subject before the Academy of Medicine, April 25, 1892, Dr. Sayre fully agreed that lateral traction and fixation was the law of treatment; that it was important that lateral traction should be applied, and claimed that he had always applied it.

I find in looking over the last edition of his book no mention of lateral traction. I find in his article of April 30, 1892, already quoted from, no mention of the application of lateral traction in any of his cases excepting Case III, 1869, and Case IV, 1864, and the case which I have already quoted, in all 407. There is no mention of it since 1872, in the L. A. McC. case, when it was not applied.

Inasmuch as Blanchard and Sayre have mentioned their use of lateral traction prior to the date of their publication, it would only be fair for me to make a statement.

From 1872 to the present time I have used lateral traction for the relief of intra-articular pressure in hip-joint disease. I have taught and applied the principle since 1874, as the note-books of my students in the colleges where I have had the honor of teaching will demonstrate. I have applied lateral traction to the splint which I have during all this period; but as I said at the commencement of this article, these are simply statements and count for nothing in the establishment of priority. Published statements are the data from which we are compelled to work.

I might further add that in the year 1884, by invitation of Dr. Schede in the Hamburg General Hospital, I put up many cases of hip-joint disease with lateral traction, as the records of that hospital will show.

I have written this article in a spirit of fairness, and I have devoted much time in looking up the subject, and my object is to place a landmark that can be referred to that will be perfectly authentic for students in the future who are desirous of exact data from which to work.

The following conclusions must be arrived at:

1. That in February, 1889, the first paper on the subject, demonstrating the application of lateral traction for the treatment of disease of the hip-joint by relieving intra-articular pressure and fixing the joint, was read by myself.

2. Following this, the paper of Blanchard, of Chicago, in the same year, in which he gives me credit for priority of publication.

3. That the case quoted by Dr. Sayre to establish a priority for himself was not treated by lateral traction applied for the relief of intra-articular pressure of the joint.

4. That the Germans who have written upon the subject only mentioned lateral traction as an argument against the Amer-

ican idea of traction as applied in the long-traction splint or by the weight and pulley, and that they publish no record of having applied it themselves, because they did not believe in any form of traction.

MEDICAL STUDY IN EUROPE FOR THE PRACTICING PHYSICIAN.*

F. R. REYNOLDS, M.D., EAU CLAIRE, WIS.

Since my return from Europe I have repeatedly been asked whether there really are any advantages to be gained by crossing the ocean for the study of medicine. I have invariably made answer in the affirmative; and I will here endeavor to give my reasons for the belief that in me lies.

Although much of benefit can be obtained in Europe by the recently graduated physician or the student of medicine, in my opinion the advantages are to the practicing physician. He who through years of labor in practice has ascertained his weak points and is fully acquainted with his shortcomings, who has arrived at the point where he is thoroughly in earnest in his search for the truth and who will be generous in his reward for services rendered and favors bestowed—to such a one, I say, the advantages are vast. Therefore to the practicing physician are the following remarks directed.

Through the kindness of Drs. H. Knapp, of New York, and E. L. Holmes, of Chicago, I carried with me letters of introduction to the most eminent ophthalmologists and otologists of London and Vienna, by reason of which my opportunities for observation and research were greatly facilitated.

My first investigations were made in London, principally in the Royal London Ophthalmic Hospital, Moorfields, and the Central London Throat, Nose and Ear Hospital, Gray's Inn Road.

I spent several weeks in that city, dividing my attention between these two institutions. I saw some fine scientific work at both places, but the advantages to myself I must admit did not meet my expectations. Of course one can look on at the operations and see the work done. But if one wishes to get into the actual practice he must matriculate for a much longer period than a physician who has left behind him a good practice can afford to spend; and it is required of him to lumber through a great deal of elementary work that he does not need. For a young physician or student the facilities for work and study in London are excellent.

I take the following from "Regulations for Pupils and Clinical Assistants" in the Central London Throat, Ear and Nose Hospital: "Clinical assistants, two to each surgeon, will be appointed from the gentlemen who have enrolled themselves for attendance on the practice of the hospital, and they must guarantee to hold the office for at least six months. They will be required to take the notes of the new cases on the forms prepared. Clinical assistants when taking these notes of new cases are on no account to practice laryngoscopy, posterior rhinoscopy, internal digital examinations, Politzer's method of inflation or Eustachian catheterization; but they will be expected to make note of what is seen in the throat by simple oral examination and in the nares by anterior rhinoscopy."

Thus it will be seen that the clinical assistants can get an excellent schooling by being in constant attendance for from six months to a year, but the other gentlemen who have simply enrolled have the privilege of peeking over the heads of attending surgeons and getting what little benefit they can, which is very unsatisfactory to say the least. The rules and regulations of the Royal London Ophthalmic Hospital are virtually the same.

In Vienna, on the other hand, ample opportunities are afforded for the actual practice. In 1889 the physicians from

*Read before the Intercounty Medical Society at Eau Claire, Wis., November 13, 1894.

countries speaking the English language who were studying medicine in Vienna organized a society for the promotion of the common interests of its members, entitled the Anglo-American Vienna Medical Association. It now has a membership of about 340. This society has a suit of rooms at No. 12 Landesgerechts Strasse constantly open for the benefit of English-speaking physicians. Here you will find the honorable secretary continually in attendance, always alert and ready with a fund of information necessary for rapidly getting at the work desired. He keeps thoroughly posted as to the private courses in progress in each branch of medicine at Das Allgemeine Krankenhaus, Children's Hospital and Die Allgemeine Poliklinik, and also has a list of suitable lodgings and boarding-houses. In connection with these rooms is a library of English literature. I joined this association immediately upon my arrival and found it of great benefit to me.

The superiority of Vienna over all other cities for the study of medicine by the practicing physician consists, first, in the centralization of medical work, the great hospitals being all in the same portion of the city and no loss of time occurring in going from one to the other; and, second, in the special facilities for post-graduate study.

Special courses for graduates of medicine, of six weeks' duration and covering every branch of the medical science, are given the year round, whereas in other schools these post-graduate courses are only occasional. The price of these courses generally is one florin (forty-eight cents) per lesson. A class is usually limited to twelve persons, so that the instructor receives about five dollars per lesson. If a person wishes instruction on any particular branch and there is no course in progress at the time, he can easily procure this instruction for his own special benefit at five dollars per lesson. Most of these special courses are given in the General Hospital, or Allgemeine Krankenhaus.

In internal medicine, besides clinical lectures by Professors Nothnagel and Schrotter, private courses are given in the wards by their assistants, classes generally being limited to six. In surgery there are general clinics by Professors Billroth and Albert and private courses by their assistants on surgical diagnosis and operations. In dermatology there are, besides clinical lectures by Professors Kaposi, Neumann and Lang, private courses on skin diseases and syphilis in their wards and at the Poliklinik. In pathology there is abundant opportunity for observation, from six to a dozen post mortems being held daily at the Pathological Institute. These may be attended free of charge. Professor Kolisko also gives a special course of demonstration in gross pathology. In bacteriology special courses are given by Professors Gruber, Paltouf and Weichselbaum. Thus we might run through with each special branch; but I have given sufficient for illustration.

I enjoyed great opportunities for practical work on the eye, ear, nose and throat. The instructor would assign cases to us and we would make our own diagnosis, treat the cases and, if operations were required, perform them; all of course under his supervision.

Other English-speaking physicians whom I met were thoroughly satisfied with the work in their lines and were loud in their praises of the advantages for Vienna.

The General Hospital is among the largest in the world, containing some 2,600 beds. The number of in-patients treated each year is over 22,000 and the number of out-patients 120,000. There are about 10,000 births and about 2,600 deaths annually. Last year 13,052 operations were performed. Connected with this hospital are 22 head physicians, 60 first assistants and 150 second assistants. From 170 to 200 American and 70 to 80 British physicians annually go to Vienna for the study of medicine.

While I found it a great pleasure and of much benefit to be able to speak the German language, the want of that ability need deter no one from seeking the benefits of medical study in the Austrian capital. In almost every department the instructors speak the English language, and they are very careful that all unacquainted with the German shall receive the full and proper instruction in English. The younger instructors and assistants are particularly earnest in their study and practice of our language.

More Cemeteries Needed.

We shall not need an epidemic of cholera when the new diphtheria antitoxine begins to get in its work.

RECURRENCE OF SCARLET FEVER IN SAME PATIENT WITHIN ONE YEAR.

JOHN B. CRANDALL, M.D., STERLING, ILL.

Helen M., aged twelve, was taken with scarlet fever in March, 1894; was under treatment for some three weeks; had an ordinary period of fever, following with exfoliation of derma; convalesced with good recovery.

The rest of the family were isolated and escaped.

In November, same year, the same patient was taken with second attack of same fever. As the patient was under my care only a few months before, I fought and tried to vary my diagnosis and think it was symptomatic fever. The mother, who was an intelligent and close observer, pointed it out and said it was the same identical fever she had had in the early part of the year. I watched the case from the early fever to the formation of the scarlet rash. The strawberry tongue, exfoliation and all of the symptoms were so well marked that I was obliged to put up a scarlet-fever card for the second time within a year for the same patient.

The throat symptoms were less prominent during last sickness. None of the others—a brother and younger sister—was taken with the disease. The sister was sent away from home and the brother did not visit her room.

I mention this as a matter of record, for it is so unusual to have this disease duplicated. I have attended hundreds of cases, but never before have met with a similar experience.

THE USE AND ABUSE OF TOOTHPICKS.

The exciting causes of caries of the teeth are invariably external, and among these decomposition of food or of mucus between the teeth holds a prominent place. It follows that removal of such matter must be beneficial. One of the means of accomplishing this is the toothpick, which, judiciously used, is of undoubted value. Food lodges between the teeth from a variety of causes: the extraction of a tooth may lead to those contiguous falling apart and so leaving spaces; improperly filled teeth, such as those left with rough edges and not sufficiently "contoured," that is, built up to the original configuration of the lost part, will form food traps; irregular position of the teeth or recession of the gums—all these will act in the same way. Attention to the dental toilette before company is certainly inelegant, but it is not necessary here to approach the subject except from a medical point of view. Of the materials used as toothpicks the best is the quill with the sharp point removed, but with this, as with all other forms, care must be observed. By indiscriminate application the gums may be so irritated and injured as to cause recession and thus increase the existing trouble, or inflammation of the tooth membrane may be caused, a most annoying condition, and one in which the still more vigorous use of the toothpick gives temporary relief only in reality to add fuel to the fire. Metal toothpicks are good because blunt-pointed, but are too thick to pass between teeth at all close together. Wood need only be mentioned to be condemned, for it is a by no means uncommon occurrence for small fibers to become detached and jammed between the socket and tooth, leading to chronic periostitis and even loss of the tooth if the condition is not recognized. An excellent substitute for the toothpick, one having few objections and one which will save many a visit to the dental surgeon, is antiseptic, waxed, dental floss silk, which, passed between the teeth night and morning, will invariably reveal accumulations which have escaped the tooth brush.—*Lancet.*

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JANUARY 26, 1895.

EDITORIAL.

MEDICAL SCIENCE VERSUS HUMANITY.

It is not often that a conflict arises between the humane treatment of a fellow-creature and the desire for knowledge whose ultimate purpose is the relief of suffering humanity. In a certain kind of fiction and in the sensational reports of college experiments and of clinical operations with which the press occasionally seeks to startle and entertain its vulgar patrons, the medical student and his teacher appear in an unfavorable light. Yet the credence placed in such "literature" must be slight, or a genuine hostility against the profession would be engendered. The falsity of such reports is, best of all, shown by the confidence which is reposed in the medical attendant by the very writers of the alleged horrors of the clinic and the amphitheater.

The profession as a whole must plead guilty to the charges of the various societies for the prevention of cruelty to animals, although such charges are usually greatly exaggerated, the intent of the experimenters ignored and the innocence of the vast majority of the profession entirely overlooked.

But in regard to the treatment of patients, the exhibition of cruelty or negligence is a rare exception. Even those physicians who are generally recognized by their colleagues to be thoroughly selfish and to be restrained neither by fear of God nor love of man, are often the very ones to whom a patient might most safely intrust himself, skill and ambition taking the place of benevolence and devotion. We recall a man, despised by his associates who knew him, hated by internes and justly feared by nurses, who nevertheless maintained a large practice and was almost worshiped by many of his patients. Such men, however, are the exception. It seems that the average man upon entering the practice of medicine assumes virtues and a sense of his respon-

sibilities that he would not have attained in any other life-work.

In striking contrast with this estimate of our own medical profession, we note in German literature a tendency to what seems to us a frank and wholly unconscious brutality. For instance, an abdominal section is made to inspect a liver, notwithstanding the almost positive diagnosis of hypertrophic sclerosis. Two pathologists, examining semen stains in preparing testimony in a case of rape, express their profound gratitude to Professor So-and-so for allowing them to inoculate a culture suspected to contain gonococci into the urethræ of two paralytics in the hospital ward of the latter. Another report describes the antagonistic action of acid solutions on the development of the germs of chancroid, fifteen persons having been inoculated in two places each, one sore being treated as indicated, the other being simply covered with a watch-glass in order to secure a control experiment.

Such a tendency is to be deprecated, not alone on the ground of sentiment, but because the habit of study purely scientific, as opposed to an endeavor at the same time to relieve suffering, blunts the perception to just those facts that are to be of vital importance to the practical physician. It is the neglect of the humane consideration of his patients that has made the typical German physician a poor therapeutist. The fact that the average medical article in a German magazine contains an elaborate history of cases, an exhaustive discussion of etiology and pathology, an exact though brief synopsis of symptoms and physical signs, a mere allusion to treatment and, as a matter of course, a minute report of the findings post mortem, is an index to a trend of medical thought that is opposed to the very existence of a medical profession. It is this trend that has, to some extent, justified the epithet "Hod-carriers of Science" as applied to our German brethren. It has brought about the purely mechanical consideration of the diseased human body. It is logical, if a man is too hot, to plunge him into cold water. The stimulating action of both heat and cold is ingeniously utilized by inducing labor by the alternate administration of a hot and a cold douche. Yet such logic needs the tempering of common sense. Just such therapeutic suggestions as these have led one of the shrewdest of American physicians to say, "I distrust on general principles any therapeutic method originating with the Germans."

We have no sympathy with those who attempt to cover their ignorance of fundamental facts in medicine by denouncing scientific study as impractical. Such men give digitalis in cardiac hypertrophy and aneurism and try to overcome ether-poisoning with injections of alcohol. Neither do we intend to incriminate the whole German profession nor to ignore the vast debt of gratitude which we owe them. Nor, again, do we advocate a neglect of scientific study and a return to the benevolent but ill-guided ministrations of a semi-medical priesthood. Let us realize, however, that the ultimate aim of all medical investigators must be practical—in other words, humane. Wherever advantage may be taken of suffering already existing, it is right—indeed, it is a duty—to do so. But we cannot condemn too severely the man who inflicts damage to gain information. Occasional infringements on the law of humanity will react on the medical profession to the extent to which they are known by the laity. A general following of such examples will remove our very reason for existence as a profession.

Modern Sacrificial Methods.

The sacrifices of Abraham, Isaac and Jacob were not in it when compared with the number of animals which must be destroyed to obtain sufficient poison to relieve an engorged population.

ABSTRACTS.

SUPRAPUBIC PROSTATECTOMY.

A. W. Mayo Robinson, of Leeds, reports (*Brit. Med. Jour.*) a series of 12 cases in which he has performed suprapubic prostatectomy during the interval including December, 1887, and January, 1894. The ages of the patients ranged from sixty-one to seventy-three years, three of them being of the latter age. Only 1 death was attributable to the operation. In this case the fatality was due to suppuration between the bladder and rectum caused by overdistention of the rectum by the colpeurynter. One patient died from senile asthenia some weeks after the operation, having fully recovered from it and having regained the power of voluntary urination by the urethra. The remaining 10 were all restored to health, with natural powers of micturition.

The author recommends the following technique: Besides aspecticizing the skin by a previous carbolic dressing and washing out the bladder with boracic lotion, he gives the patient five to ten grains of boracic acid and a little saccharine thrice daily for a few days before operation, so as to render the urine aseptic if possible. The rectal bag, by raising the prostate nearer to the manipulating finger, is of advantage, but it is important not to overdistend it, lest rupture of the rectum or inflammation of the meso-rectum ensue, for which reason he only has four or at most six ounces of water introduced. The bladder is distended with boracic lotion until it can be felt above the pubes, no fixed quantity being employed. In 2 of his cases the peritoneum was in touch with the pubes, and in 1 case it was so fixed to it that he had to deliberately open the serous membrane to reach the bladder, after which he carefully separated it and closed the peritoneal opening before incising the bladder, the patient being no worse for the complication.

In removing the obstruction he has found McGill's scissors or the cutting-ring forceps invented by Jessop to answer best for the sessile or pedunculated enlargement of the middle lobe; and for the ring-like obstruction he has used the scissors, first at one side and then at the other, so as to cut out a V-shaped portion, making a clear channel from the vesical pouch straight into the urethra, down which the finger is passed to see that the passage is clear. If the lateral lobes are much enlarged the finger can be insinuated within the capsule and the adenoid masses can be enucleated with very little difficulty. Lastly, all loose pieces of tissue are cut away and the parts are left as smooth as possible. In order to disturb as little as possible the cellular surroundings of the bladder, the edges of the vesical opening are fixed temporarily to the margin of the wound by a suture on each side before any intravesical manipulations are commenced.

Suprapubic drainage was sufficient in all cases, and it was not necessary to drain through the perineum. In the after-treatment boracic acid was given thrice daily, and the bladder was washed out once or twice daily by syringing a solution of boracic acid through from the urethra to the drainage opening. The drainage-tube was removed, if possible, on the third day, and the patient allowed to sit up within a few days of the operation. As a rule, recovery was attended with very little general disturbance or discomfort, and the urine began to be passed by the urethra soon after the patient was allowed to sit up.

The author considers that the operation of suprapubic prostatectomy in properly selected cases is one attended with less danger than is usually thought, and that if thoroughly and completely performed it is capable of affording such relief as may be in many instances genuinely termed a cure, and that in a class of cases which until a few years ago were looked upon as incurable.

Poisoning by Sulphonal.

One of the first symptoms of poisoning by sulphonal is said to be an increased dark red discoloration of the urine, due to the presence of hematoporphyrin.

THE REAL VALUE OF THE MEDICINAL PEROXIDE OF HYDROGEN PREPARATIONS FOUND IN THE MARKET.

My attention having repeatedly been called to several reports and analyses made by different chemists and published by some medical journals, I concluded to examine all the brands of peroxide of hydrogen which I could find on the market, in order to ascertain the real value of each when intended to be used as an antiseptic remedy, both internally and externally.

The reports on the subject which have come to my knowledge are quite contradictory, and my object is to impart to the medical profession the results of my experiments, which have been made on fourteen fresh samples, purchased by me in duplicate directly from the manufacturers or their selling agents.

These brands have been tested for the volume of available oxygen, the amount of residue, the degree of acidity and the amount of soluble baryta salts contained therein, as per following table:

No. 1. John Bene's peroxide of hydrogen medicinal.	*10.50	†0.1886	‡2.19	⁋None
" 2. Hydrozone	27.35	0.2180	3.11	None
" 3. Larkin & Scheffer's peroxide of hydrogen medicinal	9 65	0.1206	6.75	None
" 4. Mallinckrodt's peroxide of hydrogen medicinal	9 55	0.1408	1.43	None
" 5. Marchand's peroxide of hydrogen medicinal	16.55	0.564	1.29	None
" 6. McKesson & Robbins' peroxide of hydrogen medicinal	10.95	0.0540	0.44	None
" 7. Merck & Co 's peroxide of hydrogen medicinal	0.50	0.2418	4.57	None
" 8. Oakland Chemical Co.'s peroxide of hydrogen medicinal	10.50	0.0382	0.34	0.0017
" 9. Peuchot's peroxide of hydrogen medicinal	10.60	0.4674	1.77	0.0018
" 10. Powers & Weightman's peroxide of hydrogen medicinal	8.40	0.0830	2.03	None
" 11. Pyrozone, 3 per cent	11.20	0.0534	0.76	None
" 12. Rosengarten & Sons' peroxide of hydrogen medicinal	3.10	0.1002	0.25	None
" 13. Smith, Kline & French Co.'s peroxide of hydrogen medicinal	6.15	0 0880	2.6	None
" 14. E. R Squibb's peroxide of hydrogen medicinal	12.40	1.004	12.04	None

* Volume of available oxygen, determined by means of a solution containing 5.665 grams of permanganate of potash per liter of distilled water.

† Residue obtained from 100 c.c. of peroxide of hydrogen dried at 120° C.

‡ Acidity expressed in cubic centimeters of normal volumetric soda solution for 100 c.c. of peroxide.

⁋ Baryta found in soluble baryta salts contained in 100 c.c. of peroxide.

By referring to this table it is easily understood that sample No. 2, "hydrozone," is far superior to any other brand which has ever been made, not only on account of its containing a much larger amount of available oxygen, but also owing to the presence of a small quantity of several essential oils, the respective nature of which could not be determined, very likely because they have been submitted to the oxidizing action of peroxide of hydrogen before being used to make "hydrozone."

I attribute to this small quantity of essential oils the great superiority of hydrozone over any other brands of H_2O_2 as a healing agent.

When hydrozone is diluted with distilled water in the proportion of half and half, the resulting mixture contains about 13.5 volumes of available oxygen, and its bactericide power still remains the same as the bactericide power of sample No. 5, which contains 16.55 volumes of available oxygen.

Sample No. 14 comes next to sample No. 5, but it is readily seen that the degree of acidity is entirely too large for a preparation which is to be applied to the most sensitive diseased mucous membranes.

Sample No. 11, called "pyrozone," which contains 11.20 volumes of available oxygen, is quite similar to sample No. 6, with the exception that the latter contains a small quantity of salicylic acid. Very likely the salicylic acid has for its object to increase the bactericide power, but, unfortunately, I fear that it impairs the keeping properties of this preparation.

Acidity.—The fourteen brands which I have examined contain free acids (phosphoric, sulphuric, muriatic); and I must say that peroxide of hydrogen medicinal should never be made neutral before using, even in the most delicate cases. Neutral peroxide of hydrogen rapidly decomposes under all conditions of exposure.

The keeping properties of H_2O_2 solutions vary a great deal with the degree of purity and the percentage of free acids contained therein.

If the proportion of acid is too large, the profession well know that it acts as an irritant upon diseased surfaces. If it is too small, the solution does not keep well.

My opinion is that a standard solution of medicinal H_2O_2 must answer the following tests:

1. It should contain at least 15 volumes of available oxygen.

2. The quantity of free acid contained in 100 c.c. should require not less than 1 c.c. and not more than 3 c.c. of normal volumetric soda solution, to be made neutral. Such a small quantity of free acid is not objectionable.

3. It should not contain any soluble baryta salts.

4. It must be free from sediment.

It is to be noticed that the brands No. 7 and No. 12 are valueless.

The brands No. 8 and No. 9 are not fit for medicinal uses, owing to the fact that they contain traces of soluble baryta salts.

The brand No. 3 has a heavy sediment of sulphate of baryta, which may be considered inert toward the system, but it is certainly detrimental to the keeping qualities of this preparation.

Brand No. 14, which is sold as a 10-volume solution, is really 12 volumes, but it is too acid. Brand No. 5, which is sold as a 15-volume solution, is really 16.55 volumes, viz., about 10 per cent. above the standard.

The brand No. 2, which is sold without any mention of volume, is really a 27.35-volume solution, viz., 90 per cent. above the standard.

None of the other brands comes up to the standard, but on the contrary they run from 35 to 55 per cent. below.—*H Endemann, Ph.D., in Times and Register.*

A REPORT OF THREE CASES OF ADDICTION TO COAL-TAR DERIVATIVES.

Jeff. Suttle Davis, M.D., Health Officer of Shelley County, Montevallo, Ala., writes (*Amer. Med.-Surg. Bull.*):

During the last decade coal-tar derivatives have been largely employed as antipyretics, analgesics and anodynes. As they all have a powerful effect on the nervous system, it is but natural that they should be habitually indulged in; and as they are easily obtained, the wonder is that so few cases have been reported.

These drugs are unfortunately becoming household remedies and if their sale be not restricted much mischief will inevitably result from their indiscriminate use. Only last winter I was called to see an eighteen-month-old child almost fatally cyanosed from an overdose of acetanilid, administered by its mother. There was complete absence of the radial pulse, and the heart-beat was so feeble that it could scarcely be detected. Cold sweat bathed the body, and the rectal temperature was 97° F. After working several hours signs of reaction appeared, and I finally left the little fellow completely relieved. Atropine hypodermatically and external heat gave me the best results in this case.

As will be seen from the reports, the habit was discovered in all three cases accidentally, and it is my opinion that many cases of addiction to these various products are unrecognized by the physician. My attention was first called to the danger of their long-continued use by a brother physician, who, several years since, favored me with a report of a case of sulfonal habit. The patient was a gentleman thirty-two years of age, for whom sulfonal had been prescribed for insomnia of a year's duration. Being of a supra-nervous temperament, it was not long until he desired to be constantly under its influence, and instead of the twenty-grain dose at bedtime he took six such doses daily. His condition was pitiable in the extreme, anorexia being so marked and constant that he was gradually dying of inanition. His nervous system was a complete wreck, his condition being one of listless apathy, alternating with coma-vigil; sound sleep entirely absent; constipation marked and urinary secretion scant. Every effort to cure him had failed. I do not know how the case ultimately terminated. Since hearing of the case I have noticed reports

of several similar ones in medical journals, but never observed one in my own practice until about eighteen months ago.

CASE I.—In January, 1892, I was called to see Mr. T. W. C., sixty three years of age, who was suffering with chronic bronchitis and palpitation of the heart. Very profuse and offensive expectoration with frequent cough and much emaciation. Had suffered from bronchitis about two years, although much better at times. Cardiac complication was of only a few weeks' duration. Pulse weak and rapid, being about 160 while in recumbent position, but the slightest exertion, even the act of rising, would cause a severe palpitation. No appetite and stubborn constipation. He complained of perspiring very freely, and stated that he often had profuse night-sweats during his first sleep. Considerable cyanosis was noticed about face, which I learned was often very much more marked than on that day. Exceedingly nervous.

Prescribed codeine, creasote, fluid extract grindelia and pure cod-liver oil for the bronchitis, and for the palpitation strychnine and digitalis. Also had 10 grains of quinine daily. A rich and concentrated diet was directed, with artificial digestive agents when indicated. Very much to my surprise, there was but little improvement after a two weeks' course of this treatment.

In speaking to my druggist in regard to the stubbornness of the case, he remarked incidentally that the patient bought large quantities of acetanilid, and it at once occurred to me that I was dealing with a case of acetanilid habit. He denied the charge at first, but finally confessed. It was prescribed for neuralgia about one year previous, and, liking the effect, the patient continued to use it. At first the quantity did not exceed 10 grains daily, but at this time he was taking not less than 30 grains daily, and he was confident that he had taken a dram in twenty-four hours! His appetite commenced to fail two months before I was called, and his condition had gradually become worse until he was constantly confined to his bed.

The bronchitis existed before the habit was contracted, but I was certain that the other symptoms could be attributed to the acetanilid, and so informed him. His urine, he said, was about normal in quantity, but when examined the specific gravity was 1006 and it contained a large amount of albumin. It was tested every day for a week, and albumin was found each time. I reduced the acetanilid one-half at once and gave strychnine ($\frac{1}{30}$ grain) hypodermatically four times daily. No other change was made in the treatment, and in two weeks the quantity was reduced to 10 grains daily. He suffered with diarrhœa and had several "sinking spells" during this time, but was evidently much better.

He positively refused to consent to a further reduction in the acetanilid, although he continued to improve under the treatment, and was in a few weeks more relieved from the terrible palpitations, although his heart remained quite weak. His urine also improved, but was never entirely clear of albumin. When discharged he was able to walk about the house, and his appetite was improving. His cough was also much better. I have given him several "tonics" during the past year, and he is now able to drive into town daily. He says that he will never let acetanilid "get the best of him again," as he intends to hold it down to 10 grains daily. He thinks that quantity really makes life more enjoyable, and says he intends to take it while he lives.

CASE II.—Several months after discharging the above case I was called to see Mr. J. M., thirty-two years of age, who was ill with articular rheumatism. I had only been in his room a few minutes when I noticed that his face, especially the lips and adjacent parts, was decidedly cyanosed. His hands were cold and covered with a sticky perspiration. He was very nervous and quite anæmic. I learned from his wife that his appetite was very poor and that his bowels never acted except with cathartics. He slept very little and complained of almost constant tinnitus aurium with an occasional explosive sensation in the ear. Perspired freely during the day and at night had profusive and prostrating sweats.

Suspecting Bright's disease from these symptoms, a specimen of urine was obtained for analysis. The result of examination was specific gravity 1012, with considerable albumin. He did not believe that the quantity was materially changed. Had suffered from recurring attacks of rheumatism for about two years, though

it had never been very severe. The circulation was very weak and rapid, but there was no evidence of endocarditis or valvular trouble. He informed me that his condition was often very much better than it was on the day I saw him, the cyanosis being only occasionally present, and the other symptoms were seldom sufficiently severe to detain him from his work.

I prescribed for the rheumatism and promised to call on the following day. His wife followed me from the room and informed me that for eight months he had been taking four large capsules of acetanilid daily, and that his health commenced to fail after he had contracted the habit. It was prescribed for the rheumatism. She said that often when he had taken an unusually large amount his face would be very dark, and that at such times he often complained of a shortness of breath. These debauches always left him in his present condition. Ordinarily he could attend to his duties as clerk in a general mercantile establishment, but she found the habit was rapidly gaining on him. On my next visit I told him that I had found the drug in his urine and believed that he was taking it. He confessed at once, but would not admit that it had anything to do with his condition, as it "was necessary for him to take it."

He would fill the body of a No. 0 capsule loosely with acetanilid and pack the cap with quinine, and take from 4 to 6 of these in twenty-four hours. As each capsule contained 7 grains of acetanilid and 2 grains of quinine, his daily quantity was from 28 to 42 grains of the former and from 8 to 12 grains of the latter. He talked very freely in regard to the effects of this mixture, saying that it was a very pleasant sedative, without any bad after-effects. He could not realize that it was slowly killing him, but finally agreed to "quit a while" and watch the effect.

I reduced his daily quantity by one-half at once, which was followed by considerable depression and uneasiness about the heart, with vomiting. He was treated with strychnine ($\frac{1}{30}$ grain) hypodermatically, whisky and chloral in full doses at night. The first few nights he slept but little, and until the third day everything swallowed was promptly vomited. Whisky and liquid peptonoids were given by the rectum, as was also the chloral. Morphine hypodermatically in $\frac{1}{4}$ grain doses would always promptly relieve the "nervous spells" with which he frequently suffered during the first week. By the end of the second week the drug had been entirely withdrawn, and in one month he was in excellent health, all the unpleasant symptoms having gradually disappeared. I hear, however, from information recently received, that after going without the drug for eight months he has again contracted the habit. He continues to suffer with occasional attacks of rheumatism, and in an unguarded moment has probably taken a dose for the relief of pain and relapsed. I have not seen him in some time and understand that his health is again bad.

CASE III.—Recently, while attending a lady in labor, the husband of Mrs. M., a neighbor, called me hurriedly to the gate and requested a large dose of phenacetine for his wife. As I did not have it, I proposed to substitute something else that would relieve her until he could send to the drug store, distant a few miles. Nothing else, he said, would do, and I thought nothing more of the matter until I was in the act of leaving for home two hours later, when I received a hurried message to go to the lady at once. When I arrived I found her in an apparently alarming condition. She was deathly pale, and before I could cross the room to her bed she had a convulsion. No coma followed this convulsive attack, and in a few moments she was again sitting on the edge of the bed, vomiting profusely. In a few minutes she was walking the floor and occasionally screaming that she was dying.

It was not difficult to recognize the hysterical element in this case, but I had a hasty consultation with the husband and learned the cause of her alleged approaching death. For several months she had been taking phenacetine regularly, having commenced it for the relief of an almost constant pain in the top of her head. On the night before while taking a dose she had accidentally lost her supply. As she had never been without it before, neither she nor her husband anticipated the great disturbance to follow. On the following morning while at breakfast she began having "nervous spells," as he expressed it, and told him to go to town for some phenacetine. Soon after this she commenced to vomit and remarked that she

felt "dead all over." It was then that he came to request a dose of the drug from me, and as I could not supply him he made a hurried trip to the drug store for the phenacetine. Unfortunately the druggist's supply had also run out, but he was expecting to receive some by the evening train. When he informed his wife of this on his return she "immediately grew alarmingly worse" and had several hard convulsions at once.

She had had more than a dozen when I reached the house. She was very pale and was covered with a cold perspiration. Pulse 170 and almost imperceptible at times; respiration 30 and spasmodic. She had vomited an almost incredulous amount, and was at this time vomiting a glassy-looking mucus, mixed with bile. None of the convulsions was followed by coma. Kidneys acting profusely, and during the last convulsions before my arrival she had passed a very large watery discharge from bowels. Pupils enormously dilated, but she was so nervous that I could not ascertain the amount of reaction to light. I at once administered morphine sulphate, $\frac{1}{4}$ gr., atropine sulphate, $\frac{1}{150}$ gr., and digitalin. This quieted her considerably in about fifteen minutes, but it was necessary to repeat the morphine in an hour, at which time I gave $\frac{1}{4}$ gr. without atropine. After this she slept several hours and in the mean time the phenacetine was secured.

In a few weeks I was called to see her little girl, and took advantage of the opportunity to question her in regard to the habit. As stated elsewhere, she had been addicted to the phenacetine for about seven months, and her daily quantity at that time was between 15 and 20 grains. She was very positive that her health was better than before she commenced it. Her complexion was extremely bad, though anæmia was not present to the extent observed in the other cases. Circulation at this time weak and pulse 124; never had palpitations or profuse sweats. Appetite tolerably good, but digestion not what it should be. Constipation is present, but she claims that it existed before habit was contracted. Kidneys act very well. Does not sleep as she should, but does not have disagreeable dreams. Had not menstruated in two months, but may be pregnant. Last time the flow was very scant, which is very unusual. Is often quite dizzy, especially when attempting to move after sitting some time. Has frequently narrowly escaped falling on such occasions. I obtained specimen of urine and found on examination that it contained no albumin, although the specific gravity was about 1012. Have tested urine several times since with similar result. I learned that the attack she had on the first morning I saw her was the first that she had ever had. A neighbor who had known her since childhood informed me that she had never been in the least hysterical.

The patient positively refused to discontinue the drug, saying that her health was better than it had been in years. The husband and neighbors, however, could not agree with her on that point, as only a short time before she was a healthy, buxom country girl.

In summing up these cases, it will be observed that a weak heart, anæmia, indigestion, insomnia, constipation and neurasthenia were conditions more or less marked in each case. Albuminuria was present in two cases, while in the third case the specific gravity was quite low. In two cases there was an almost constant perspiration with occasional prostrating night-sweats. A marked recurring cyanosis was also observed in two cases. These were the most prominent symptoms and can very reasonably be accepted as those to be expected in similar cases.

It is also seen that the symptoms following the withdrawal of these drugs in cases of addiction resemble very closely those following the withdrawal of the narcotics in similar cases, *i.e.*, depression, insomnia, vomiting and diarrhœa.

Strychnine hypodermatically, with morphine when necessary to relieve "nervousness" and chloral per rectum at night, gave the best results in the treatment.

Chloral Hydrate in Hæmoptysis.

Dr. J. Palvy has tried chloral hydrate in 15 cases of hæmoptysis. Doses of 15 to 25 grains (1 to 1.6 grams) were injected per rectum. They are reported to have produced an effect within one-half to three quarters of an hour.

The chloral hydrate, besides, seemed to be also a valuable prophylactic. The author describes several cases in detail and recommends a further trial of the remedy. —*Amer. Medico-Surg. Bull.*

THE TREATMENT OF TYPHOID FEVER.

Of all the branches of the medical sciences, it is hygiene upon which we have to look as most promising study and the branch of medicine to which belongs the future; for notwithstanding the great progress that has been made within the last few decades in the etiology of diseases, the treatment in many instances is not much further advanced than it was several decades ago. We still have to rely more upon scientific nursing than upon the healing powers of drugs, and in many instances the patients will do better without any medication whatever excepting, perhaps, when it is used for the psychical effect upon the patient. The rules laid down by Sir William Gull could not be improved upon at the present day. Gull's views with regard to the treatment of typhoid fever were as follows:

1. Typhoid fever is a disease which runs a more or less definite course. It cannot be stopped or cured by medicines.

2. The chief thing to be done at the outset of an attack is to send the patient to bed, so as to save strength from the beginning.

3. No strong purgative medicines are desirable.

4. As the fever develops and the strength grows less light food should be given at short intervals—*i.e.*, water, toast-water, barley-water, milk and water, light broths (not made too strong or too gelatinous).

5. If there be restlessness or much agitation of the nerves, wine (port, sherry or claret) or brandy in moderate doses at short intervals. This must be directed medically, but in general it may be said that the amount required is that which induces repose and sleep.

6. The bowels may be left to themselves. If unmoved for twenty-four or thirty-six hours a lavement of warm water may be necessary, but this will be directed medically.

7. The restlessness or wakefulness in fever is best remedied by the careful giving of wine or spirit with the food or in hot water. Sedatives such as opium are inadmissible—mostly injurious.

8. The bedroom to be kept at a temperature of 62° to 65° F.

9. Great care is necessary to keep the bed clean and sweet. This is most easily done by having a second bed in the room, to which the patient can be removed for two or three hours daily while the other is thoroughly aired and the linen changed.

10. All fatigue to be sedulously avoided. No visitors admitted and no other person but a nurse and one attendant to help her.

11. Patient's room never to be left unattended for a moment, as in the delirium of fever he may jump from bed and injure himself.

12. As to medicines and the treatment of complications, the immediate medical attendant must be responsible.

13. As it is possible that the discharges from the bowels in typhoid fever may be a source of contagion, it is desirable that before being thrown down the closet they should be largely mixed with Condy's fluid or some other disinfectant. On the same principle the strictest cleanliness must be observed in the sick-room.

14. There is no reason to believe that typhoid fever is contagious from person to person in the ordinary way. The largest experience shows that it does not extend, like an ordinary contagious disease, to nurses or others attending upon patients suffering under the disease.—*Med. Review.*

M. Pasteur on Rabies.

M. Pasteur addressed the following reply to a lady who wrote to him for information respecting the symptoms of rabies (*Med. Rec.*): "M. Pasteur has had the pleasure of receiving your letter. The bite of a dog is only dangerous when the dog has got rabies. If there is any doubt in respect to this, the manner in which it may be found out is the following: Put the dog that has bitten where it can do no further harm. Have it examined by a vet., and if it has the rabies its characteristic symptoms will not be long of being observed, and the animal will certainly die in eight days. If at the end of that time no symptom of rabies has been observed, the bite cannot cause hydrophobia and there is no reason that the animal should be destroyed."

HEMORRHOIDS—OUTERBRIDGE'S OPERATION.

Administer a laxative on the second night preceding the day of operation, which will cause a thorough evacuation of the bowels and an interval of rest of from twelve to twenty four hours. The rectum will then be empty at the time of operation, avoiding the excessive peristalsis and rectal tenesmus generally complained of. Unless necessary, do not cut away hair, as the short hairs cause considerable irritation for two or three weeks after operation. Make the anæsthesia sufficiently profound, in view of the fact that the sphincter reflexes are almost the last to be abolished. Dilate the sphincter ani with the thumbs, bringing the hemorrhoidal mass into full view. Thoroughly scrub the anal region and wash the mucous membrane well above the operative field with tinctura saponis viridis and warm water. In cases with only external "tabs" or with three tumor-like masses inside the sphincter ani, insert the point of a tenaculum into the most prominent portion of the "tab" or tumor, or grasp it with a pair of thumb-forceps. Make enough traction at right angles to the gut to clearly define the mass. Surround it with the blades of a pair of scissors (curved on the flat) pressed well toward the muscle, and remove the diseased tissue with one or two cuts. Unite the elliptical raw surface by a continuous catgut suture. Amputate and suture each distinct mass in the same manner.

In cases where the whole hemorrhoidal "inch" is dilated, thoroughly dilate the sphincter, causing the hemorrhoidal ring to protrude from the anus. Grasp a part of the mass with the thumb-forceps, and with the curved scissors cut away a strip of mucous membrane and hemorrhoidal tissue down to the muscle, following the line of the muco-cutaneous junction all around the lumen of the gut. Remove a second or third strip if the size of the mass renders it necessary. If external hemorrhoids are also present, in order to prevent recurrence of pruritus and the numerous discomforts usually following the ordinary operation in that region, remove a strip of skin down to the sphincter ani in the same manner. Bring together the free edges of the skin and mucous membrane with a continuous catgut suture, taking a double stitch at two or three points in the circumference of the bowel to interrupt the sutures and avoid the necessity of tying. Should bleeding occur at any point immediately after suturing, an extra suture at that point will at once control it. If during the removal of the mass any vessel bleed excessively, it can be quickly controlled by at once beginning to suture.—*A. E. Gallant in Mathews' Med. Quart.*

On the Inheritance of Stuttering.

Instances of the development of stuttering in children of stuttering parents in which the influence of environment and imitation can be positively excluded are of sufficient rarity to make the following case, reported by Professor Epstein (*Prag. Med. Woch.*), of interest:

A woman consigned her ten-day-old child to the charge of a foundling asylum, from which it was immediately sent into the country, where it remained until six years of age. The parents then reclaimed the boy. He was therefore brought back to the asylum, where it was found that the intelligent, well-developed child stuttered so badly as to render his speech at times almost unintelligible. On the arrival of the parents it was discovered that the father, who had never seen the child, suffered in a marked degree from the same trouble. He had stuttered, he asserted, since childhood; no other members of his family had been afflicted in the same way.

Anal Incontinence.

Dr. Gersler (*Med. Rec.*) reports a case of rectal incontinence in a boy aged seven that was complicated by prolapse of the bowel, in which he succeeded in producing a cure by twisting the bowel upon its axis 360° after having dissected the anus and two and one-half inches of the rectum loose from the surrounding tissue. Strict asepsis with primary union and careful suturing of the anus in its new position are the two points that must be observed to make the operation a success.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Treatment of Peripheral Neuritis.

Professor Leyden believes that in the case of neuritis following acute specific diseases, care during convalescence as to nourishment, rest in bed and avoidance of over-exertion contribute to prevent its occurrence. "Etiological treatment" (removal of the cause) in neuritis due to alcohol or lead and treatment of the primary malady as in diabetes is of the first importance. There is no specific remedy for multiple neuritis, and treatment by drugs does not play a very important part. Owing to the fact that rheumatism is not infrequently an element in the etiology, salicylate of sodium and other anti-rheumatic drugs had been used, without producing any good results in the majority of cases. Iodide of potassium was of use only now and then, and mercury was of doubtful value. Antipyrin, phenacetin, exalgin, euphorbia and methylene blue were sometimes of use for the relief of pain, but it was often necessary to resort to morphine, chloral, sulphonal, etc. Strychnine, formerly much used, but lately fallen into the background, deserved to be tried; by increasing the excitability of the affected muscles it favored the return to normal functions and nutrition; it ought especially to be resorted to in progressive cases in which the respiratory movements were threatened. Leyden prefers to use it as a subcutaneous injection, 1.70 gr. to 1.20 gr. twice daily. Massage and baths were valuable auxiliaries which were indicated, especially the latter, in the later stages of the disease. General hygienic treatment was of much importance. Rest—as a rule rest in bed—was of the first importance in the early stage; in the later stage, feeding. Finally, in the latest stages of all, moral suasion, rousing the patient's latent energies, was often of great value. Passive movements and encouraging the patient to make active movements were generally attended with better results than massage in this stage. Electricity, formerly used too much, was now used too little, but its usefulness was greatly limited by the fact that in many cases the pain caused was too great to permit the treatment to be continued.—*Berl. Klin. Woch.*

Treatment of the Vulvitis of Little Girls.

In the *Revue Obstetricale et Gynecologique* the treatment of the vulvo-vaginitis in children is summarized as follows: During the first stage, when the parts are inflamed and swollen, they should be bathed with starchy and emollient lotions and covered with compresses saturated with a boric solution 1:100, a sublimate solution 1:10,000, or carbolic-acid solution 1:100. The active inflammation being arrested, the parts should be well dried with absorbent cotton and dusted with a powder of iodoform, 4 grams, tannin, 1 gram, and bismuth subnitrate, 6 grams; the labiæ should be kept separated by a pledget of absorbent cotton. When the inflammation extends into the vagina, about 30 grams of the following mixture should be injected: Glycerin, 100 grams, alum and cocain hydrochlorate, each 1 gram. The injection must be repeated after each act of micturition and must be followed by the iodoform insufflation. If desired, the injection may be replaced by the introduction of a small vaginal suppository made from the following, divided into 15 small filiform bougies having a diameter not exceeding 5 mm.: Iodoform, 8 grams; gum tragacanth and cocoa-butter, each 10 grams. Finally, the general treatment is of the greatest importance. The children should be built up and sent to the country or seashore. Cod liver oil, iron iodide and the phosphates are especially indicated.

What Small-Pox Can Do.

At the time of the announcement of vaccination by Jenner small-pox caused more than one-tenth of all the deaths of the human race. Fifty million people died in Europe from small-pox during the eighteenth century (*Med. Rec.*). In the sixteenth century the disease appeared in Mexico, and 3,500,000 of the population yielded up their lives in a few years, leaving some provinces almost depopulated. In 1707 in Iceland 18,000 died in one year, the entire population being but 50,000. Seventy per cent. of the people of Greenland died of small-pox in 1734. Small-pox is the most fearful disease with which the human race has ever been scourged. Macaulay tells us it was always present, filling the churchyards with corpses and leaving on those whose lives it spared the hideous traces of its power. "If a modern traveler," says Dr. Hyde, "could be transported to London in the early part of the present century, no peculiarities of architecture, dress or behavior would be so conspicuous as the enormous number of pock-marked faces he would encounter at every turn." It spared neither rich nor poor and even invaded the palace of the king.

The Relation of Eczema to the Mucous Membranes.

Von Sehlen calls attention (*Monat. f. prak. Dermat.*) to the relation which exists between eczema of the skin and certain diseases of the adjoining mucous membranes. Inflammation of the nasal mucous membrane, chronic catarrh of the external ear, conjunctivitis, balanitis, inflammation of the anal mucous membrane with the formation

of fissures, are some of the affections which may arise from the extension of an eczema. In the treatment of these the author has found ichthyol of great service. The paper concludes as follows:

1. Chronic eczema of the skin may attack the adjoining mucous membranes and pro duce upon them apparently independent affections

2. Eczema of the lips, catarrh of the exter nal ear, eczema of the lids, and a certain form of conjunctivitis are to be regarded as special localizations of the eczematous process, and are to be treated accordingly.

3. Certain inflammatory conditions of the anal mucous membrane and of the genitalia in both sexes seem to stand in close, if not causal, relationship to eczema of the skin.

A Study of Certain Remedies in Chronic Epileptic Insanity.

A physician in the Tuscaloosa Hospital for the Insane summarizes (*Amer. Jour. Insanity*) the effects of treatment by various means in 55 cases of epilepsy and insanity as follows:

1. Borax, antipyrin, acetanilide, phenacetin, and many other alleged anti epileptic agents are, save in rare cases, without influence over the course of chronic epilepsy with insanity.

2. Beta-naphthol is occasionally beneficial, but probably not more so than catharsis.

3. The bromides will postpone the occurrence of the convulsions, but in most cases do more harm than good.

4. In dealing with the maniacal attacks, seclusion may be necessary. Sedatives should be employed very rarely, if at all.

5. The best single remedy in the status epilepticus is blood-letting. Of drugs the most valuable is chloral.

Cannabis Indica.

Mackenzie (*La Semaine Med.*) speaks highly of cannabis indica in all forms of cephalalgia. He has found it act favorably even in the severe headache attending cerebral growths. In chronic uremia, where opium is contraindicated, it is especially serviceable. He has found the remedy to be almost a specific for that continuous form of headache which begins in the morning and lasts all day. In these cases the pain is generally dull and diffuse, but marked by occasional exacerbations. While it is rarely severe enough to interfere with occupation, yet it constitutes a source of constant annoyance to the patient. In such case the author administers morning and evening from one-twelfth to one-half grain of the extract in pills. If these doses are not sufficient, he gives one grain in the evening and one-half grain in the morning. In very obstinate cases the dose is still further increased, the larger dose always being taken in the evening, until relief is afforded or toxic symptoms become manifest. In some instances Mackenzie combines gentian, cinchona or hydrobromate of caffeine with the cannabis indica. In various neuralgic affections, gastralgia, enteralgia, the pains of tabes the drug often proves very useful.

In skin diseases associated with intense itching, particularly senile pruritus, where local applications fail to relieve, cannabis indica is often used with great benefit. The author has rarely observed any untoward effects from its use, nevertheless, to avoid toxic manifestations, the drug should be given at first in small doses, the latter being gradually increased.

Chloroform in the Treatment of Chorea.

When the convulsive movements of chorea are of sufficient severity to interfere with the digestion of food or sleep is prevented by the attacks, there is great danger of rapid exhaustion, and even death may be apprehended In such cases chloroform will prove a veritable boon. Not only will the anæsthetic induce perfect relaxation and relief from the present attack, but the insensibility produced by it often passes into natural sleep, and the patient awakes refreshed and completely rested, with marked abatement of the hitherto constant movements. The improvement in some cases is marvelous. Not only is the sufferer allowed a much-needed rest by this means, but the attacks are delayed, their intensity mitigated, nourishment may be taken with relish, and a decided change in condition results. In the beginning it may be necessary to use the chloroform three or four times daily, but as improvement occurs only one administration in the twenty-four hours will be found necessary. Usually a month is required before the permanency of the cure is established.—*Louisville Med. Jour.*

Treatment of Delirium Tremens.

In the New York *Medical Journal* Bellamy concludes an article as follows:

1. Delirium was controlled with greater rapidity and safety by trional than by other hypnotics.

2. In the majority of cases a marked stimulant effect was observed, possibly on account of the methylic elements which enter into the composition of the drug.

3. On account of the low temperature noted in all cases, trional must possess antipyretic properties, thereby simulating its allies of the phenol group.

4. Trional was always well borne by the stomach, and in one case was rapidly absorbed when administered per rectum.

5. No unpleasant after-effects were observed, and in all cases recovery was speedy with the exception of two.

Face and Tongue Varicose Veins.

Dr. Ida R. Gridly, of Collinsville, Conn., reports (*Med. Rec.*) the case of a fifty-nine year-old woman whose tongue on both the upper and lower surfaces was much ridged, furrowed and studded with irregular elevations, some the size of a large pea. These elevations were soft, purple and but little covered with the ordinary coating of the tongue. There were

five large elevations on the right side and two on the left. The anterior portion was more affected than the posterior. The lower lip and the buccal mucous membrane were studded with similar small purple elevations. When she was born a small purple tumor was noticed underneath the chin. When she was twenty-three years of age a little red speck the size of a pin's head appeared on her left cheek, and was diagnosed as a "spider cancer" by a female quack calling herself a "cancer doctor." She applied a "fire plaster to draw out the cancer," and produced a large sore which did not heal for two months. A scar the size of a quarter of a dollar still remains. Immediately after the sore was made varicose veins appeared on the tongue, the cheeks and the side of the neck. Several physicians thought this treatment caused the varicose condition. It seems more probable that there was a congenital tendency. She has also varicose veins under the pubes and near the anus. At times the veins on her tongue and cheeks will swell up and become quite annoying. Once, twenty years ago, she burned her tongue with a piece of hot meat and opened one of the veins, causing a hemorrhage which was stopped with some difficulty. Twice since then she has spit up blood, coming apparently from the throat, not from the mouth. Aside from these annoyances this condition gives no trouble.

Ergot in Phthisical Hyperidrosis.

A writer in *La Semaine Medicale*, dissatisfied with the results obtained with the means usually employed in phthisical hyperidrosis, conceived the idea of trying ergot in large doses on account of its well known vaso-constrictive action. His success surpassed his expectations. With the large majority of his patients freshly pulverized ergot, administered at bedtime in doses of 5 grams (1¼ drams), completely arrested or at least greatly diminished the sweats. A single such dose did not always suffice, in which case it was repeated in an hour. Some of the author's patients took the stated dose even for fifteen consecutive days without any inconvenience. Only exceptionally was the drug found to be powerless against the night sweats.

Primary Nasal Diphtheria.

Dr. Charles W. Townsend (Boston *Med. and Surg. Journal*) says:

Primary nasal diphtheria may occur of a very mild type. These cases are likely to go unrecognized, for the following reasons:

1. Resemblance to ordinary coryzas, a membrane not being noticed in some cases except by careful scrutiny.

2. The normal or only slightly elevated temperature often present, with but little constitutional disturbance.

3. The intermittent character of the nasal discharge, absent for several days and then starting up again.

4. The apparent recovery, even with cessation of nasal discharge, while Klebs-Loeffler bacilli are still present and capable of transmitting the disease in a fatal form to others.

5. The difficulty of always finding the bacilli in the nose, even when they are present.

Bacteriological examinations in all suspicious cases of nasal discharge should be made.

In primary nasal diphtheria there should be prolonged isolation, together with a refusal to consider a case cured until several consecutive negative cultures have been obtained.

Sodium Nitrite as a Therapeutic Agent.

Gordon Sharp (*Practitioner*) draws the following conclusions from his experience with sodium nitrite:

1. Sodium nitrite, being stable, may replace the less stable amyl and ethyl nitrites.

2. It dilates all the arterioles rapidly and so relieves the heart quickly.

3. Disagreeable symptoms may be overcome by combining it with ammonia water or spirit of chloroform and small doses of morphine.

4. It is most useful in anginal affections and in irregular heart action.

5. To obtain the most benefit from its use it should be continued some time after all symptoms have passed away. By this means the heart is able to regain its tone and so to repair itself.

6. The maximum dose is four, or the most five, grains, and generally one or two are enough.

7. Graves' disease would appear to be aggravated by it.

8. Bronchitis and asthma, in the author's experience, are not benefited by its use.

SURGERY.

Pott's Disease in Children

Pott's disease in children is so often recognized so late in its course that all hope for improvement is futile. The early symptoms and signs which should always be looked for are laid down by Dr. Dillon Brown in the *Archives of Pediatrics* in the following list of different points:

1. The pain, general disability and sickness are out of proportion to the apparent amount of spinal disease.

2. The onset is alarming and the progress of the disease is more rapid than in tubercular caries—the paralysis being an early symptom and the deformity appearing even in a few weeks after the beginning of the symptoms.

3. The local pain is intense; and the peripheral pains, the deformity, the extreme spinal disability and the paralysis, including incontinence of urine and feces rapidly grow worse in spite of rest in bed and instrumental support.

4. Secondary disease soon appears, rapid emaciation and marked cachexia are seen, and the patient does not live more than six or eight months.

Whether a vertebral caries is due to syphilis or to tuberculosis is of immense importance

as regards prognosis and treatment. In both diseases the symptoms are almost identical, and the diagnosis must be based upon the history, the presence or absence of other evidences of syphilis and the result of treatment. In tuberculosis there is more likely to be an evening rise in temperature, and the pus and refuse may contain tubercle bacilli. Syphilis is suggested by nocturnal pains and the involvement with chronic disease of some other joint or joints or some other part of the spine.

Rules for Trephining in Injury of the Skull.

1. All cases of depressed fracture, either simple or compound, require trephining and elevation, whether there be pressure symptoms or not.
2. All punctured fractures and gunshot wounds imperatively indicate the use of the trephine.
3. In simple fracture of the skull where any symptoms of brain trouble persist exploratory operation should be done.
4. In all cases of local injury to the skull, whether fracture or bruise, followed by evidence of inflammation of bone or persistent symptoms of brain irritation, or of pus between the bone and dura, the trephine should be resorted to.
5. In every case of localized injury to the head where unconsciousness persists for more than an hour, exploratory operation, including opening the skull if necessary, should be done.
6. The appearance of stupor some hours after a head injury indicates meningeal hemorrhage and requires trephining at the point of injury if known or at point indicated by cerebral localization, the middle meningeal being the usual source of trouble.
7. Even in very extensive injury to the head operation should be made, since removal of fragments, restoration of normal contour and cleaning of injured tissues can add but little to the danger and may save life.
8. In every case of doubt exploratory operation is justifiable.
9. Compound fractures, with or without apparent depression, demand enlargement of the wound and careful exploration.—*St. Louis Clinique.*

Lumbar Puncture for the Removal of Cerebro-Spinal Fluid.

Dr. William Browning (Boston *Med. and Surg. Jour.*) says:

1. The method is simple, easily practiced and rather attractive.
2. In itself it is usually without danger.
3. By it we certainly can draw off cerebro-spinal fluid.
4. The quantity removed at short sittings has been from one to one and a half ounces in adults.
5. This without doubt represents the amount of free fluid usually present in the lower vertebral canal even when occluded above.
6. In internal hydrocephalus the relief, if any, is but very temporary. In the common form due to tubercular meningitis the result is not worth the trouble, while in the closed or sacculated forms it must rather do harm than good.
7. As a diagnostic means, for example in suspected meningeal hemorrhage, it is valuable. As an index of pressure it may also be worth noting.
8. It is worth further trial (*a*) as a passing relief in brain tumor not complicated by hydrocephalus; (*b*) as a substitute for trephining in progressive dementia; (*c*) in certain spinal troubles; and (*d*) possibly as a means of applying medication directly to the spinal meninges.
9. In conclusion, it may be said that while admissible in all cases of brain-pressure, there is as yet no established indication for this procedure except for diagnostic purposes.

The Treatment of Floating Kidney.

Riedel (Reineboth in *Cent. f. Chirur.*) performed nephrorrhaphy in eight patients. As a result of this experience it was found that sutures made to include the renal structure and surrounding adipose tissue were insufficient for the purpose, and suture of the fibrous capsule alone by means of catgut was subsequently substituted. This, however, only permits of fastening of the lower half of the organ, or that portion which projects below the twelfth rib, and fixation of the upper half must be accomplished by some other method. This is done by splitting the fibrous capsule for its entire length at the posterior edge of the kidney, loosening it from its attachments to the latter as far as possible, and tamponing the space thus formed by means of a strip of iodoform gauze. The gauze is pushed as high up as possible between the exposed renal surface and the diaphragm. The remainder of the wound is also tamponed with iodoform gauze. The strip of gauze is allowed to remain for several weeks, and upon its removal two broad granulating surfaces are to be found lying opposite to each other. These become attached in the further progress of the healing, and the kidney thus becomes secured along its whole posterior border. The results thus far obtained are sufficiently encouraging to warrant further trial of the method.

Diabetes and Surgical Operations.

It is the experience of every surgeon that while operations upon some diabetic patients may be apparently as harmless as operations upon healthy individuals, they are in some cases accompanied by disastrous results. The tissues of diabetics are a particularly favorable soil for the development of bacteria, inflammation and gangrene being often the inevitable result of surgical procedures. If asepsis is a necessity in any operation, no matter how insignificant, it is pre-eminently so in diabetic patients, and gangrene may often be prevented by operating under the strictest aseptic precautions. Antiseptics, on the contrary, are as much as possible to be

avoided on account of their irritating properties. It is of much importance for the surgeon to know in what cases of diabetes it is justifiable to operate and when it is not advisable to undertake an operation, and with regard to this question the observations made by Dr. Reynier, of Berlin, are of much interest. According to the experience of this author, operations are particularly fatal in cases of diabetes in which the reflexes are absent. Of 40 diabetic patients operated upon 15 died, and in 13 of these the reflexes were absent and died of gangrene, lymphangitis and phlegmons of a gangrenous nature. Of the remaining 2 one died of a phlegmonous inflammation which was developed from a panaritium, the other in consequence of a carbuncle which had been treated with sublimate and boric acid. The carbuncle healed, but suddenly sugar disappeared from the patient's urine, albuminuria set in and death occurred from uremia. Reynier differentiates between hereditary diabetes which is characterized by an excessively developed panniculus adiposus, but where the function of the muscles is preserved, and atheromatous diabetes in which the muscles are infiltrated with fat and degenerated. The latter occurs at about an age of fifty, while the former makes its appearance between the twenty-fifth and thirtieth year. There is less danger in operating upon the atheromatous form of diabetes than upon the diabetes due to an infection of the nervous system and pancreas. Gangrenous manifestations appear after operation at any stage of the disease, but the resistance offered by the tissues to an operation or any kind of irritation becomes less and less as the reflexes disappear.—*Med. Review.*

Anesthetics.

Anesthetics have been quite the absorbing topic among English practitioners at times during the past year. Commissions continue to be appointed and bring in unsatisfactory reports, but the whole tendency and purport of the discussion has been very decidedly to elevate ether above chloroform. One of the most recent elaborate reports on this question is that of the commission established by the London *Lancet* to investigate the whole subject of the administration of anesthetics, and Dr. Dudley Buxton draws the following deductions from it:

"1. That the death-rate under anesthetics heretofore has been unduly high, and may, by improved methods and greater care, be lowered.

"2. That ether when properly given from an inhaler, permitting graduation of the strength of the vapor, is the safest anesthetic in temperate climes for general surgery.

"3. That nitrous oxid gas should be employed for minor surgery and should replace chloroform in dental surgery.

"4. That chloroform when given by a carefully trained person is a comparatively safe body, but is not in any case wholly devoid of risk.

"5. That no age or nation is free from danger under anesthetics.

"6. That the perils of anesthetics, however slight, demand that the undivided attention of a duly qualified and trained medical man should be given to the administration of the anesthetic."

Oxalic Acid as a Germicide.

"As is perhaps known," says Dr. Mary Sherwood in the Philadelphia *Polyclinic*, "at the Johns Hopkins Hospital the routine preparation of the surgeons' hands consists in thorough washing, followed by immersion in a solution of potassium permanganate until stained a deep red-brown. To remove the stain they are then placed in a warm saturated solution of oxalic acid. Repeated bacteriological tests have shown that this method is very effective."

A series of experiments by the author to test the relative germicidal powers of the two solutions, however, seems to indicate that the real germicide was the solution of oxalic acid. Using bits of surgeon's silk dipped in cultures of staphylococcus pyogenes, it was found that potassium permanganate in saturated solution did not sterilize them, either at the room temperature or at a temperature of 45° C. (113° F.), by exposure of from one to ten minutes. On the other hand, oxalic acid in saturated solution, at a temperature of 40° to 45° C. (104° to 113° F.), sterilized the infected threads exposed to its action for one minute, showing the oxalic acid to be the more powerful germicide.

THERAPEUTICS.

Sulfonal a Reliable Sleep-Producer.

Authorities are still somewhat divided as to the relative merits of sulfonal and trional, some expressing a preference for the one, some for the other. In a discussion which recently took place before the Therapeutical Society of Paris, and which is reported in the *Medical Week*, Dr. C. Paul summarized his views as follows:

"I have employed both sulfonal and trional, and I prefer the former, which is the best remedy for nervous insomnia unaccompanied by organic lesions. It has no ill-effects, either on the heart or lungs, and is excellent in the treatment of patients suffering from heart disease, but useless for consumptives, inasmuch as it does not prevent coughing. The sleep which it procures is sound and waking is easy and without nausea. I do not think any advantage would be gained by substituting for it either trional or even tetronal."

Dr. Bardet, who participated in the discussion, has also found sulfonal a satisfactory remedy. Dr. Brough (*Jour. Mental Sci.*) suggests the use of this drug as a means of inducing insane patients who refuse food to eat voluntarily. He observed in five cases of severe melancholia, in which the patients had repeatedly and for a long time refused food, that after each administration of sulfonal, which was given as a hypnotic in the

evening, they voluntarily resumed eating. The author desires that others should test the correctness of his observation. Attention to the value of sulfonal in the sleeplessness of neurasthenic persons has recently been directed by Dr. G. H. Savage (*Brit. Med. Jour.*), who regards it as "the least harmful drug," and by Dr. F. S. Thomas (Omaha *Clinic*), who obtained excellent results from its occasional use together with a small opiate in these cases.

GYNECOLOGY.

Rules for the Introduction of Instruments into the Uterus.

Dr. C. S. Bacon (*Amer. Jour. of Obs.*) says:

1. Do not expect to complete the preparation of the patient with less than fifteen minutes of hard work.

2. Never make the examination at the first visit of the patient. Instruct her how to take a vaginal douche, and direct her to use sublimate douches twice a day for three or four days. If immediate examination is required, let it be done at her home or in a hospital with all the preparatory details of a surgical operation.

3. Thoroughly disinfect the external genitals and surrounding skin.

4. Disinfect the hands and instruments, including the irrigating tip, which should be a glass tube.

5. Wash the vagina with a solution of lysol or creolin. In the office I have found Tooker's bed-pan most useful. With two fingers, either with or without sterilized gauze or cotton, thoroughly scrub every part of the vaginal wall.

6. Introduce a Neugebauer speculum, which is better than any form of Cusco's bivalve, for it is asepticizable and better than a cylindrical speculum, as it is much easier to work through.

7. Disinfect the cervical canal by means of a cotton swab, using first the liquid soap, then a strong creolin solution, and finally alcohol. Never introduce an instrument without seeing the cervical canal.

I believe that the carrying out of these rules will present all except post-partum, post-abortum and gonorrheal endometritis and salpingitis.

Early Diagnosis of Cancer of the Cervix Uteri.

Dr. Ernest Herman (*Brit. Med. Jour.*) says that as secondary growths occur later and less frequently in the uterus than in any other part of the body, the early recognition and removal of the diseased area is of the utmost importance The readiness with which the vaginal portion of the cervix may be examined makes it possible to detect diseases early and to gain successful results from treatment. The early diagnosis of cancer is so important that we are justified in making an unusual hemorrhage or discharge in a woman who has borne children a reason for a vaginal examination. The use of the microscope in establishing a diagnosis of cancer has decided limitations, and while it will occasionally reveal cancer in doubtful cases, negative evidence of cancer by microscopical examination should not be relied upon, and an opinion had better rest upon the local and general symptoms. As a rule, the first signs of cancer are hemorrhage and leucorrhœa; pain and loss of flesh come later. Cancer that begins as an outgrowth from the surface of the cervix resembles a growth of warts, papillæ or granulations, and the surface feels uneven or rough. The disease may start as an ingrowth beneath the surface. It may be detected by an angry, livid, red spot, the surface of which is at first quite smooth. This angry color depends upon the vascularity caused by the new growth and upon its tendency to break down, which leads to minute hemorrhages into the growth before the breaking down is extensive enough to make a breach of the surface. The livid surface of a cancer spot bleeds on being rubbed, so that a smooth, dark-red spot, bleeding on contact, is very suspicious. This is the earliest stage of cancer, and if a nodule can be felt the suspicion is stronger. When the cancer has advanced to a cauliflower-like growth the diagnosis is quite certain.

Gangrene of Vagina from Iron Applications.

The danger of making (*New York Med. Jour.*) applications of preparations of iron to mucous membrane of the vagina in the attempt to check uterine hemorrhage is pointed out by Dr. Charles E. Nammack, of Gouverneur Hospital, New York. He cites the case of an out-patient who applied for help at the clinic suffering from extensive gangrene of the vagina. She had been treated two days before by a practitioner who had then inserted a tampon of cotton soaked in tincture of chloride of iron. She was found to be markedly anemic, with rapid feeble pulse and temperature between 100° and 104° with chills. Locally the whole vaginal mucous membrane, including that of the vaginal portion of the uterus, was covered with thick blackish sloughs. Douches and boro-glyceride tampons were used and the dead tissue removed as quickly as possible. The underlying granulating surface was dusted with iodoform and the vagina packed with iodoform gauze. Later the use of the glass plug will be necessary to prevent stenosis.

Garrigues ("Diseases of Women," 1894, p. 343) refers to a case where a tampon soaked in medicated liquor ferri chloridi produced an exactly similar condition to that found in this patient.

R. A. Murray, at the meeting of the Section of Obstetrics and Gynecology, New York Academy of Medicine, reported having known undiluted persulphate of iron to cause cicatrices in the vagina, and advances this as a possible cause of atresia in the vagina in some cases.

OBSTETRICS.

Treatment of Vomiting of Pregnancy.

Lutaud (*Revue Obstet. et Gyn.*) states that vomiting of pregnancy is best treated by cocaine. The action of this drug is often strengthened by combining it with antipyrin. Thus the following prescription:

Chlorohydrate of cocaine.....	grs. iss
Antipyrin	grs. xvj
Distilled water.....	℥ iv

Sig.: One teaspoonful every half-hour until vomiting ceases.

If the stomach will not tolerate this quantity of liquid, ten drops of a one and a half or two per cent. solution of cocaine are administered, repeated at one or two hour intervals.

At times the application of cocaine to the os is extremely valuable. The following prescription may be used:

Hydrochlorate of cocaine.....	grs. xvj
Extract of belladonna.....	grs iv
Vaseline.....	℥ ss

Cotin's method of dilating the os with the finger sometimes causes immediate cessation of vomiting. Occasional success will follow Routh's procedure, which consists in exposing the uterine neck ny means of a speculum and painting with tincture of iodine. In cases of moderate severity the following mixture will be found serviceable:

Tincture of iodine.....	℥ ij
Chloroform	℥ ij

Sig : Five drops night and morning at meal-times, taken in Seltzer water.

Care of the Navel in the New-Born.

Schrader discusses this subject in a paper which was read before the Obstetrical Society at Hamburg (*Cent. f. Gynak.*). He says the question as to the best treatment of the stump of the navel cord probably seems to many unimportant, because the frequency and danger of infection through the navel wound are not appreciated. Unfortunately we do not yet possess sufficient statistics on the subject. Recently, however, Ehrendorfer has published a large and very valuable collection of cases bearing upon this point, from the obstetric clinic at Innsbruck. Of 1,764 children born there, 95 died; and on 81 of these an autopsy was made. Infection of the navel was demonstrated in 16—therefore in 16.48 per cent. of all that died, or in about 1 per cent. of all the children under observation. Probably even this percentage is too small if all the facts were known. Ehrendorfer rightly brings out that without an exact autopsy the cause of death in the new-born is frequently overlooked, especially since the illness due to infection very often is complicated by pneumonia, icterus, gastro-intestinal catarrh, etc., and these sequelæ, unless an autopsy is made, are assigned as the cause of death. It is probable, therefore, that a much higher percentage of the new-born die of infection through the navel than is now believed. To prevent this Ehrendorfer recommends strict asepsis at the time of severing the cord and afterward, and that the effort be made to secure rapid and complete mummification of the stump. This latter is to be attained, first, by thorough protection of the stump from moisture, and, second, by its exposure, so far as possible, to the air. To avoid moisture Schrader advises that bathing of the infant, except for the cleansing immediately after birth, be entirely dispensed with until the stump has fallen off and the navel has healed. It is not so easy to permit free access of air, but to attain this as far as possible the stump should be wrapped in a piece of linen or mull, dry, not oiled. Eross found in his observations and experiments on nearly a thousand infants in the clinic at Budapest that a dry linen cloth is better for the stump than one oiled. This first dry dressing is usually not changed. The band is not to be too firmly applied, and should be frequently raised to allow access of dry air. If the stump does not do well in this simple way, as is apt to happen with a large amount of Wharton's jelly, Schrader powders it well with dermatol; and after falling off of the cord the navel wound is kept powdered with dermatol for several days.

In the discussion that followed this paper Windmuller said he dresses the navel cord with dry charpie, using powdered boracic acid if there is a bad odor, but only the charpie again after the odor disappears.

Aly had had good results by dressing with a powder of alum and boracic acid; equally useful is powdered sugar.

Lomer also employed powdered sugar, and had never seen a bad result in 500 cases.

Hotte was opposed to omitting the daily bath, because it was in every way beneficial to the new born.

In reply, Schrader did not consider the bath so necessary that it could not be omitted for the first eight or ten days without disadvantage. Infants, he found, got along as well without it, and in fact less often developed snuffles.

Early Signs of Pregnancy.

It has long been taught that the diagnosis of pregnancy in the first three months is very difficult or even impossible. This Dr. Charles P. Noble contradicts in the Philadelphia *Polyclinic*. In his experience careful abdominal palpation will make it out as early as the sixth week or at any time between the sixth and twelfth weeks. This sign, he says, has never failed him in his dispensary work, but almost all of these cases came in to see if pregnancy existed, and as they were illegitimately pregnant it was possibly rather an easy guess. The shape of the virgin uterus is pyriform, while a uterus in which there is an ovum but a few weeks old will have grown sufficiently to cause the body and fundus of the uterus to assume a spheroidal shape.

The conditions which he found to simulate pregnancy were hematometra, which is very rare and usually occurs at the time of puberty; and intramural fibroid tumors, which

on account of the asymmetrical shape given to the uterus may be left out of the question. When pregnancy occurs in a uterus where there is already a fibroid or if the uterus be jammed between tumors of the ovary, then the diagnosis is very difficult, and when the patient is very stout palpation is not easy. Still, in general, he thinks a pregnancy can be told with certainty in the first twelve weeks, and he emphatically makes this statement in view of his large experience.

Expulsion by "Quilling."

A correspondent sends the following, for the truth of which he vouches: A young doctor who began his practice in Texas, west of Houston, was called to a confinement case in which he, being green and nervous, naturally had some trouble, the patient seeming unable to make the supreme effort for final expulsion. The only other occupant of the wretched quarters was an old crone in a sunbonnet, who was silently but steadily rocking herself near the foot of the bed. Finally the old woman croaked out: "Doc, I wouldn't bother any longer with that woman. I believe I'd quill her and have done with it." The medical man, not knowing what quilling meant, answered that he did not quite see the necessity for that yet. The old woman repeated this suggestion several times, until finally the nervous, exasperated man turned angrily on her and said: "Madam, I'll be d—d if I will do it. If you want to quill her you can do so, but I won't." The crone took from the wall a turkey wing, and drawing a feather from it proceeded to fashion something like a long quill toothpick, and filling this with snuff from her own private stock leaned over the patient, and as the next pain came blew the snuff into the woman's nostrils. Quick as a flash the woman responded with a giant sneeze, and the child was born with the sneeze. "Thar," said the old woman radiantly, "I knowed mighty w that thar bust would make her break her holt." And it did, to the great instruction of the attending physician.—*Med. Rec.*

PHYSIOLOGY.

The Physiology of the Spleen.

Volpius (*Beitrage zur klin. Chirurgie*) has arrived at the following general conclusions concerning the physiology of the spleen:

1. Histological study of the normal splenic tissue shows the possibility, but not the certainty, of the entrance of colorless cells in the circulation from the spleen. It is evident that the red cells undergo disintegration in the spleen, but there is no ground for assuming that they are formed in the spleen.
2. Comparison of the blood of the splenic artery and vein shows no positive difference.
3. In acute general anæmia the spleen shows signs of increased activity.
4. Removal of the spleen causes a transient decrease in the number of red and an increase in the number of white blood cells.
5. The thyroid gland has no vicarious relation to the spleen.
6. The lymph nodules and the bone marrow acquire an increased blood-forming activity after extirpation of the spleen.
7. The regeneration of blood is retarded after hemorrhage in persons without spleen.

These conclusions, though contradicting certain accepted teaching, offer little that is new, but are of value in that they are based upon accurate scientific data and corroborate much that has already been done. Unfortunately, our knowledge of the physiology of the spleen is still left in a state of confusion.

The Treatment of Abortion.

G. Wyeth Cook (*Am. Jour. Obs.*) says that while the subject is a commonplace one, he considers it one of the greatest importance to the general practitioner. It is generally conceded that everything should be done to prevent a threatened miscarriage. If this is impossible, it becomes necessary to completely evacuate the uterus as quickly as possible. When there is considerable hemorrhage the tampon should be used. This is best accomplished by inserting some iodoform gauze in the cervix and then packing the vagina with long strips of sterilized gauze. Should not the whole uterine contents be expelled when the tampon is removed, the writer advocates strongly the radical method of treatment, the immediate removal of the uterine contents by means of the finger introduced into the uterus, or the curette, under the strictest antiseptic precautions. Neglected miscarriages are the most fruitful sources of pelvic diseases.

In removing the secundines the finger is the best instrument to employ. If the cervix is not sufficiently patulous to admit of easy entrance of the finger or curette, the necessary dilatation may be produced by means of a dilator or laminaria tents. Failure to remove the entire uterine contents allows a festering hot-bed of infection to remain within an organ which is ever ready to absorb the products of such decomposition.

In conclusion, the writer states that many of the cases of abortion seen by him have been criminal in their origin, and he asks: What is the duty of the physician to the State in matters of this sort? I believe it to be the moral duty of the physician to preserve inviolate facts that he may have learned in his capacity as physician. Yet criminal abortion is a crying evil, and the law does not excuse the doctor from revealing what he may have learned in his capacity of physician, notwithstanding the information he may have was communicated only because it was necessary to an intelligent understanding of the case. And should a woman die from the effects of a procured abortion, should the physician so state or should he falsify the death certificate? There can be no doubt as to his duty in this last case. But the woman surviving, I am not so sure as to the course he should pursue, because of the apparent difficulties in legally establishing the facts.

PATHOLOGY.

Biting the Nails.

Dr. Berillon, as the result of an extensive inquiry, confirms his previously expressed opinion that onychophagia and similar habits are generally associated with degeneracy. The frequency of onychophagia varies greatly in different institutions. In some, 2 or 3 out of every 10 children are addicted to biting their nails. A careful examination invariably reveals signs of degeneracy. The children are usually less healthy in appearance than others, presenting deformities of the skull and anomalies of the teeth and ears. In such subjects the teachers notice a marked antipathy to physical exercises and games requiring effort. They write poorly and show marked inferiority in respect to manual dexterity. They are slow to learn; they are incapable of continuous application; in fact, they always exhibit an inferiority in some direction or other. The disciplinary measures usually resorted to to correct bad habits are powerless in this; in the majority of cases only hypnotic suggestion seems to be capable of effecting a cure. The habit of biting the nails sometimes persists until late in life.—*Med. Fortnightly.*

Contribution to the Study of the Etiology of Varicocele.

B. S. Talmey, M.D. (*Amer. Medico Surg. Bull*), is quoted as saying that masturbation is almost always the pathological cause for varicocele. There can scarcely be a greater unnatural irritation of the nerves than that caused by onanism. During such an irritation the testicles being in a secretory condition are supplied with a greater amount of blood, and anything that increases the amount of blood to the testicles is surely a cause for varicocele. Through the continued high pressure the walls of the vein become lax, flabby and unresisting and the vessels enormously dilated. The elastic and contractile tissue of the venous walls is absorbed and replaced by a low grade of connective or fibrous connective tissue. The same condition as in the spermatic cord in the male is found in the broad ligaments, as the ovarian veins in the female are the analogue of the spermatic veins in the male. That varicocele is frequently formed in women after pregnancies is agreed by most writers on this subject. But the author does not remember having read about a case of varicocele in a virgin such as he once saw in a girl, whom he immediately suspected of masturbation. The sexual organs were all in a normal condition, and yet she complained of a dragging sensation along Poupart's ligament and in the vagina. The broad ligaments were thickened.

BACTERIOLOGY.

Vitality of the Typhoid Bacillus.

According to Uffelmann (*Cent. f. Bakt.*) typhoid bacilli resist drying for a long time. From his investigations he concludes that these micro-organisms retain their vitality in a dry state for many days—in ordinary earth, 21 days; in street-sweepings, 30 days or more; in sand, 82 days; on wood, 32 days; and on linen over 60 days. In moist media it is very probable that the microbes would retain their power of growth still longer. The same investigator proves that typhoid bacilli may be carried by the air as well as by the clothing, and that they are thus capable of infecting milk, water and various foodstuffs.

Uffelmann's mode of distinguishing the typhoid bacillus may be briefly stated as follows: In the microscopical examination low powers, not exceeding 100 diameters, are employed. A careful note is taken of the movements of the microbes and the shape of the colonies as compared with typical colonies. The fact that typhoid bacilli do not induce fermentation in 2 per cent. lactose gelatin is also utilized, together with the characteristic growth upon methyl violet gelatin.

NEUROLOGY.

The Cause and Premonitory Symptoms of Cerebral Hemorrhage.

Dr. C. L. Dana (*Boston Med. and Surg. Jour.*) reports 100 consecutive cases of apoplexy with hemiplegia observed at his clinic at the Post-Graduate Hospital and 79 cases of apoplexy with autopsy observed in Bellevue Hospital. Thirty of the latter came under his personal care and observation.

Of 100 non-fatal cases 36 were due to syphilis. The special characteristics of the cases due to syphilis are that they occur in early life, that they are often multiple in character, and that the pathological condition underlying them is usually a thrombosis and softening.

So far as his experience and records went, cerebral hemorrhages are rarely repeated, and it seemed as if in many cases the rupture of an artery changed the vital conditions, as it certainly does the personal habits, so that the attack exercised a conservative influence upon the individual and actually tended to prolong life.

BOOK REVIEWS.

Lippincott's Magazine for January, 1895.

The complete novel in the January issue of *Lippincott's* is "The Waifs of Fighting Rocks," by Captain Charles McIlvaine. The scene is laid in the mountains of West Virginia, and the tale is one of adventure, love and jealousy among the mountaineers.

"By Telephone," a stirring newspaper story by Francis C. Regal, shows how a plucky reporter defeated a conspiracy and brought the criminals to justice. "A Question of Responsibility," by Imogen Clark, deals with delicacy *vs.* life-saving in a lodging house.

The other stories belong to Christmas, and are offered at the right time instead of a

month beforehand, as is the usual magazine custom. These are "Mrs. Santa Claus," by Marjorie Richardson, "A Prodigal Friend," by S. Elgar Benet, and "Mrs. Risley's Christmas Dinner," by Ella Higginson. Each of them is in the spirit of the season, though the last is in a minor key.

"Christmas Customs and Superstitions" are collected by Elizabeth Ferguson Seat. Edgar Fawcett recalls "New Year's Days in Old New York," and Edith Duff "Empress Josephine's Happy Day," ninety years ago.

In "The Ducks of the Chesapeake" Calvin Dill Wilson tells all about the canvas-back before he is shot and after. Gilbert Parker offers a study of "Herbert Beerbohm Tree," the actor. F. M. B., in "With the Autocrat," recalls some notable private utterances of Dr. Holmes, and M. Kaufmann discusses "Socialist Novels."

The poetry of the number is by M. S. Paden, Alice Brown, Kathleen R. Wheeler and Susie M. Best.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JANUARY 6, 1895, TO JANUARY 12, 1895.

The leave of absence for seven days granted Captain Reuben L. Robertson, Assistant Surgeon, is extended twenty-one days.

The leave of absence granted First Lieutenant Charles Lynch, Assistant Surgeon, is extended one month.

First Lieutenant George D. De Shon, Assistant Surgeon, will proceed from Fort Logan, Colorado, to Fort Douglas, Utah, and report for temporary duty.

Ordinary leave of absence for one month and fourteen days, in addition to the extension of leave of absence on surgeon's certificate of disability granted him, is granted Captain Adrian S. Polhemus, Assistant Surgeon.

Leave of absence for three months on surgeon's certificate of disability is granted Captain Wm. C. Shannon, Assistant Surgeon.

Leave of absence for one month is granted First Lieutenant Henry C. Fisher, Assistant Surgeon.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING JANUARY 15, 1895.

Carter, H. R., Surgeon; to assume temporary command of Cape Charles Quarantine, January 7, 1895; relieved from such duty, January 14, 1895.

Perry, T. B., Past Assistant Surgeon; to proceed to Delaware Breakwater Quarantine Station for temporary duty and to rejoin station (Cape Charles Quarantine) upon completion of same, January 14, 1895.

Wertenbaker, Past Assistant Surgeon; granted leave of absence for seven days, January 3, 1895.

NEWS AND MISCELLANY.

Pennsylvania State Medical Society.

The members of the Medical Society of the State of Pennsylvania who wish to read papers at the meeting to be held at Chambersburg May 21 to 24, 1895, will please send their names and the titles of the papers they wish to read to the chairman of the Committee on Scientific Business, Dr. Charles W. Dulles, 4101 Walnut Street, West Philadelphia.

The committee desires papers to be absolutely no longer than ten minutes.

At the last meeting a large number of interesting papers were not read because those preceding them were too long, and it is to be hoped that those who prepare papers for the coming meeting will condense them as much as possible. The laws of the society permit each writer to occupy twenty minutes, but it will be of advantage if the members of the society do not avail themselves of all their privilege.

MEDICAL AND SURGICAL
REPORTER.

No. 1978. FEBRUARY 2, 1895. Vol. LXXII—No. 5

ORIGINAL ARTICLES.

THE PRETUBERCULAR AND PREBACILLARY STAGES OF CONSUMPTION.

CHARLES MANLY, A.M., M.D., Denver, Col.

The steady decrease in the mortality from consumption during the years of the decade just passed is attributable not so much to improved methods of treatment as to a better knowledge of the disease itself and the measures which have been put forth toward its prevention. The importance of an early diagnosis in such cases as must arise is apparent.

In attempting a paper under the difficult title of "Pretubercular and Prebacillary Stages," I will not arouse unnecessary antagonisms or limit the freedom of preconceived opinions by essaying to state just what part the bacillus plays in this degenerative process. The pathological enthusiasm aroused by the discovery of Koch's bacillus should not blind us to the fact that there are other elements than the bacillus and the changes which by its presence are wrought in the tissues and fluids where it domiciles. There are other elements, I say, necessary to the production of this disease.

The bacillus is ubiquitous, yet only a part of the human race falls victim to its ravages. The individual equation is the necessary factor. Some individual weakness is necessary to be added to the bacillus. This weakness may be inherited or acquired. The question of hereditary influences has already been ably considered by Dr. Ruedi. Many persons with inherited tendencies escape the disease, even after prolonged exposure, until some impairment of the general health opens the door to the invasion of infecting bacilli. Certain inherent conditions, I believe, followed by certain incipient stages constituting a negative intoxication (recognizable), precede the developed symptoms of established phthisis, just as a stage of intoxication precedes the lethal symptoms of a large dose of opium.

There is something in the physique of these individuals necessary to the production of phthisis—something preceding bacillary infection—something which realizes the fact of that infection and makes it possible, and a something which, being the "personal equation," determines the course, character and effect of such infection. This condition of health I have dared to call "the pretubercular stage." It has been variously described in the past as, by Dr. Rokitansky, "the phthisical habitus;" by others as the "tuberculous predisposition," "susceptibility," "favorable soil," "lack of resisting power," "tubercular diathesis," "good culture medium." There are still other forms of expressing this same condition of ill health. "That condition which makes the human tissues a receptive soil—a favorable culture

medium for the tubercle bacillus—that condition which of old was called 'diathesis' and now 'susceptibility,' is itself a disease—a departure from the *normal*—and I believe it to be the most important element in the morbid complexus termed tuberculosis. It is the element requiring the greatest care in prophylaxis—the most intelligent and faithful treatment." *

But what do these terms mean? Metschnikoff attempted to show that it is all summed up in a lack of leucocytes to destroy the elements of contagion—a weakness in the microbe-killing activity of these blood scavengers. Others claim that "susceptibility" consists of a want of certain bio-chemical constituents of the tissues, fluids and blood plasma. A generally embryonal condition of the connective tissues—abridgment of the lymph spaces and increase in the solids of blood. Dr. Cutler advances the theory of "acid dyspepsia"—an acetic-acid fermentation resulting in a yeasty condition of the blood. Others admit that "inherent weakness" is modified tuberculosis, the bacillus being transmitted with the ovum, lying dormant for years and held in abeyance awaiting a favorable opportunity to develop. Such opportunity is afforded when the surrounding tissues are enfeebled, either by an injury or by some "critical period" of life, when it develops into genuine tuberculosis.

These definitions and theories as to the pretubercular stage are inadequate. We seek, therefore, to overcome the difficulty by defining the condition as one of impaired or defective nutrition.

In tuberculosis generally the first symptom is loss of weight. This is usually the most prominent symptom and one which is directly proportionate to the progress or severity of the disease. Nutrition is defective in quantity, leading to atrophy and wasting; it is altered in quality, causing deterioration and softening of the tissues.

The diagnosis of this condition is most difficult. Incipient tuberculosis, simulating as it does almost every other disease, is not easily distinguished, especially from typhoid fever. It is often mistaken for gastric disturbance or rectal stricture.

The changes in the lungs themselves may be small or great, but they are generally confined to the periphery, where it is not noticeable; or, where the bronchial tubes are concerned, a mistaken diagnosis of bronchitis is made. But as in the first and second stages the disease is so thoroughly masked at times as to awaken no suspicion, so in the prebacillary stage the same condition obtains, and the diagnosis should be made objectively. The rational signs are of great weight.

After catarrhal pneumonia, or "la grippe," or concomitant with a chronic irritation due to foreign substances inhaled incidental to an occupation like cigar-making or coal-mining or any sort of mill work, we find a condition aptly described as "chronic inflammation," and vulgarly known as "phthisic," "winter cough," etc. We know the change in the pulmonary tissues consists as follows: "Cells, the product of inflammation, accumulate in the alveoli and bronchi and crowd upon each other, becoming densely packed, and thus by mutual pressure are destroyed and cause at the same time decay or injury to lung tissue."

Such conditions we know present but little auscultatory information, but auscultation is not diagnosis. As an eminent authority has expressed it, "I esteem rational symptoms as of greater weight than those signs eliminated by auscultation."

Associated with progressive loss of weight, nutrition suffers from a loss of appetite and the well-known languor which precedes typhoid fever. Patients have often said to me, "I feel exhausted when I awake. A few hours in the early morning I feel stronger, at eleven o'clock exhausted again, and the same at four in the afternoon." One cannot claim that such a statement of symptoms is pathognomonic of any particular disease, but I do say it is *especially true of phthisis*.

Perhaps in no class of cases is the element of lassitude so marked and so diagnostic as in children, who, though they may not be the offspring of tuberculous ancestry, may have the so-called predisposition stamped upon them in belonging to a large family of children born of a mother whose periods of lactation lapped over the periods of pregnancy four or five months each year.

The physician who fails to diagnose the pretubercular stage with incipiency in such a child at any time when loss of

*S. Solis Cohen.

weight and appetite and languor are the symptoms, or when the child has a chronic cough incidental to measles or pertussis, commits a double wrong—to the physician's judgment and to the patient's confidence.

It may not be amiss to remark again upon the importance of careful diagnosis in these cases of measles and whooping-cough. When measles exhibit a decided tendency to pulmonary inflammation, the distance to phthisis is not great. The respiratory murmurs may never return to normal clearness. Associated with the frequent relapses into bronchial troubles, we find induration and caseation with diminished expansion. This is evidenced by a short but easy cough, rapid respiration without evident dyspnœa. This, however, is not the time nor the occasion for a description of the tuberculous child.

I will not attempt to discuss at length the histology or pathology of this condition of ill health. Nor will I take up the subject of treatment, which is practically that of phthisis itself and will be discussed in a succeeding paper. I pass at once to my conclusions:

That there is a pretubercular stage.

That it is something more than mere predisposition or susceptibility.

That it is a mitigated form of consumption.

That it is either hereditary or acquired.

That, other things being equal, continued loss of weight is suspicious of oncoming tuberculosis.

That the keynote of this condition is impaired nutrition.

I deprecate the preponderating importance given to the bacillus, whereas this condition of health occupies the position of a primary etiological factor to which the bacillus is secondary in importance.

I deprecate the supercilious superficiality with which many physicians veil the seriousness of this condition under the name of "bronchitis."

SCIATICA (?)—MANIA A POTU—PLEURITIS WITH EFFUSION OCCURRING IN PHTHISIS—TUBERCULAR OR SYPHILITIC LARYNGITIS.*

CHARLES CARY, M.D., BUFFALO, N. Y.

This patient exhibits an interesting and puzzling condition, and I present him, not to illustrate a well-marked and logically treated clinical type, but for the sake of some valuable hints which may be of help in practice.

The patient is Irish; aged forty-five; single; twenty years in this country. His family history has no bearing on the case except perhaps that one brother died of Bright's disease at fifty. Six years ago he had a chancre, which was followed after five months by a general cutaneous eruption lasting eight months. At this time he had pain in the left hip, running to the knee, and several similar attacks have followed at irregular intervals. On entering the hospital twelve days ago he complained of pain and tenderness in the popliteal space, inability to extend the thigh, and the left leg was somewhat atrophied. He has always been a drinking man and has occasionally gone on a spree.

The pain and the immobility of the hip were so marked yesterday that I asked Dr. Park to see the patient, to determine if there was anything in the way of an actual lesion of the joint. No positive signs of a surgical condition of the joint were found, though it seemed to me from the way in which he held the thigh that there might be some effusion. The temperature at no time has reached 99°, which enables us to exclude any high grade of inflammation, rheumatic, septic, etc.

At this time and for some days previously the patient would swing the entire trunk rather than let us move the hip joint, which was held rigidly in a state of semi-extension. Having made a probable exclusion of disease in the joint itself, we

*Clinical lecture at Buffalo General Hospital.

looked further for an explanation of his symptoms. Midway between the tuberosity of the ischium and the trochanter major the slightest pressure caused great agony. This suggested sciatica, but today the signs are contradictory, though I believe that the symptoms manifested by the patient have been perfectly genuine. I can now move the leg and thigh quite freely without causing pain. I can extend the knee and flex the thigh—in fact, the patient is more comfortable with the thigh moderately flexed toward the abdomen than in the ordinary position while sitting. Yet this is the position in which the sciatic nerve is stretched, and if there were sciatica we should expect more comfort from relaxing the nerve than from extending it. The best non-operative means of stretching the sciatic nerve is to raise the thigh as I am doing now, but to a higher level. It seems to me that there is no atrophy of the limb, nor do I detect any loss of muscular tone.

Although there was a pretty clear history of syphilis, I did not care to put the patient upon specific treatment till more positive manifestations occurred. He was given Rochelle salts every morning, was kept in bed and counter-irritation was made over the hip. For the first five or six days he made no improvement. Then bitartrate of potassium was given in small doses (1. gm. t.i.d.). Under this treatment, though I do not pretend to say due to it, he has improved. In this treatment we were influenced by the fact that the urine contained albumin and granular casts. The albumin has diminished in quantity and there is no evidence of general dropsy. The patient has had prolonged antisyphilitic treatment in the past, and he lacks a very characteristic symptom of the joint pains of syphilis, namely, that the pain is not greater at night.

I would like to correct a notion that one might naturally form from hospital studies and from remarks often made as to the frequency of syphilis. If your practice is among the better classes of the community you will not meet with more than a few new cases of this disease in a year, although the cases that you do have will last a long time, so that you will practically always have them with you. The disease pervades all ranks of society, sparing neither prince nor pauper, but it is in the improvident class from which hospital wards are recruited that syphilis is particularly rife.

MANIA A POTU.

This patient entered the hospital suffering from acute alcoholism. He later became delirious and unmanageable and passed through quite a long course of delirium tremens. Once he was almost recovered, but about ten days ago he had a relapse. While he has again recovered from the active delirium, he is in an excited state which I think calls for treatment in an insane asylum. He is gentle, but he labors under delusions, and you have noted that he has twice attempted to climb the stairs leading up into the amphitheater. He keeps asking me about things which I have never said to him, and he often speaks to people who are not present.

In the majority of cases of insanity it is not easy to fix absolutely the cause, but here alcoholism is plainly responsible. Alcohol may bring about actual physical lesions in the brain or its membranes, especially in the way of pachymeningitis, or the disturbance may be functional. This patient has shown no signs of an inflammatory process. His temperature has been normal. I do not believe that he is in the first stage of paresis, but think that he will recover from what will, I hope, be a lesson to him not to repeat his previous experiments with alcohol.

Such cases often resemble those of locomotor ataxia, but in this instance there is no difficulty in the differential diagnosis. The gait is not very uncertain, the patient can stand and walk with his eyes shut, and his reflexes are not lost. His general condition is good and the prognosis is therefore favorable.

PLEURITIS WITH EFFUSION OCCURRING IN PHTHISIS.

This patient entered the hospital nearly seven weeks ago with a very abundant pleuritic effusion in the right chest. She is thirty-six years of age, a housewife, of native birth. Her father is alive and well; her mother died of consumption at thirty-eight years of age. Of two brothers and three sisters, a brother died of consumption and a sister of erysipelas. The patient herself was healthy till two

years ago, when she had an attack of grippe. She has never recovered perfectly, has lost thirty pounds and has coughed and expectorated frothy sputum. She has been troubled with night-sweats, chilliness in the morning and feverishness later in the day. Her appetite has been poor and her bowels constipated.

On entering the hospital her pulse was 120, weak and soft; her temperature 100° F. The physical signs were as follows: Right lung anteriorly, sibilant breathing and subcrepitant râles, friction sound below and to the left of the nipple, bronchovesicular breathing; posteriorly, right lung, tubular breathing and flatness. The fluid on the right side accumulated very rapidly until there was marked flatness and the respiratory murmur had almost disappeared on that side. The friction of course disappeared with the separation of the pleural surfaces by the fluid. The patient has since gained in weight to 108 pounds at the present time. The fluid has disappeared and respiration has been restored over the base of the lung, but the physical signs have changed at the apex.

On percussion, at the right apex when the lungs are filled with air there is a peculiar note. The air is driven out through the nostrils, giving a nasal quality to the crack-pot sound. On auscultation I hear loud, cavernous breathing, with the same metallic quality when she breathes through the mouth. It is accompanied by râles, which have increased very much since the last examination. At the base of the lung matters have very much improved. The lung is resonant and the breathing fairly good. The temperature chart is significant. The morning temperature is about 97°, the evening temperature 2° higher, with a maximum of 102.5°.

The question was raised as to the advisability of withdrawing the fluid. On account of family history, her mother and sister having died of tuberculosis at about her age, I did not want to run any risk of perforating the lung and allowing the exit of tuberculous matter into the pleura. There were certainly areas of consolidation, and with the tubular breathing heard at some points and absent at others, it seemed that there were adhesions at some places and effusion separating the lung and chest wall at others. There is no better culture medium for tubercle bacilli in the body than the peritoneum, and the pleura is almost as good.

Whether my fears as to the immediate danger of puncture were well grounded or not, the condition has cleared up without operative interference. At the same time, with the past history and the present condition of the lung itself, the outlook is unfavorable.

TUBERCULAR OR SYPHILITIC LARYNGITIS.

This patient is thirty-eight years of age; a Norwegian lumberman; married. His father died at the age of seventy-three, his mother at the age of eighty-two, of unknown causes. He has two brothers living and well. He came to this country twelve years ago. He has been healthy till two years ago, when he took cold and was in bed three days with pains in the ears and throat. Since then he has suffered with sore throat, and last June his throat began to pain him more severely, especially on swallowing. Three weeks ago (about January 1st) he became too weak to continue at work, being unable to swallow enough solid food for proper nourishment. He smokes considerably, but is temperate in the use of alcoholic beverages and denies venereal history. The tongue is coated; the bowels constipated. The urine on admission had a specific gravity of 1020, was dark red, of urinous odor and acid reaction and contained neither albumin nor sugar. His voice has become more and more husky and, finally, his breathing has become obstructed. He has improved somewhat, he says, since he has been in the hospital.

There has been some doubt as to the diagnosis. Several who have made laryngoscopic examinations have diagnosed syphilitic laryngitis, while I have rather held the trouble to be tuberculous, although differing with those more expert in diseases of the throat. It seemed to me that the man had a bad-looking chest, an examination of the lung revealed areas of impaired respiration and dullness, and Dr. Benedict examined some of the sputum and found tubercle bacilli present. Still, we cannot depend entirely on finding tubercle bacilli in a hospital patient's sputum. In two or three cases in which we have been surprised to find them present it has turned

out that some one else had used the patient's sputum cup. If the case is one of syphilis, as Drs. Cott, Rochester and Hinkel have all decided from the appearance of the larynx, I am firmly convinced that it has been accidentally acquired, for the patient seems perfectly straightforward in his denials of infection. We can elicit no history of an eruption nor find the evidence of a primary lesion. His habits of life have not been wanton, and he does not give a single sign of syphilitic disease except in the throat. The epiglottis is inflamed, the false vocal bands are engorged and the cavity is filled in with granular matter, showing that an extensive ulcerative process is going on. The man has improved somewhat on antisyphilitic treatment, but we should expect the alteratives to have a favorable influence on such a grade of inflammation even if not specific. It is possible that we have to deal with a mixed syphilitic and tubercular infection.

The laryngeal breathing is so loud that it is transmittted to the lungs and might mislead one into thinking the lungs more diseased than is the case. Laryngeal breathing is a loud, tubular sound with a high, whistling character. The respiratory sounds are exaggerated on the left side, and in each interscapular region I have marked an area of loud breathing. In the axillary regions the breathing is diminished. On heavy percussion in the left infraclavicular region, while the patient breathes deeply, I can elicit a crackpot sound—that is, I can expel the air through the larynx by the blow of the finger. I do not believe, however, that this sign indicates a cavity in every instance. I find the loud subcrepitant râle which is to be expected in any case in which the lung is breaking down. The tubular quality of respiration is due, I have no doubt, to the laryngeal disease. It is not surprising if this sound can be heard on the back row of seats that it should be transmitted to the lungs. The râles, I am confident, are formed in the air-passages under the stethoscope, yet I would not be willing to book them as positive signs of tubercular disease. It may be that the patient originally had syphilis of the larynx and that tuberculosis developed later. The temperature range is from 98° to 101.5°, which favors the latter diagnosis.

EXERCISE, REST AND FOOD IN THE TREATMENT OF PULMONARY CONSUMPTION.*

WM. H. BURR, M.D., WILMINGTON, DEL.

The interesting papers on "Rest Cure in Pulmonary Consumption," by Thomas J. Mays, M.D., appearing in THE MEDICAL AND SURGICAL REPORTER June 17, 1893, and "The Management of the Convalescent Stage of Phthisis," in the October number of the *American Medico-Surgical Bulletin*, are accountable for the following, which embodies partly my experience and partly my theory in the treatment of the same subject. And it is from the exercise side of the subject that I wish to say the most.

It is notable in the treatment of any subject in medicine how great a tendency there is to attempt to generalize or reduce to a system the treatment of certain diseased conditions belonging to it. This is perfectly natural, and is only the result of the desire for that order and system which, when carried out in other branches of science, is productive of the largest results. But the treatment of any diseased condition is so large a subject and has to do with so many uncertain elements that are not thoroughly understood, that the attempt to classify and bring into order is very often more destructive than beneficial.

It is astonishing how many different ways of seeing things there are for different persons, and what opposite results are arrived at by equally intelligent people. Possibly this is the result of the omission

* A portion of this paper appeared in the American Medico-Surgical Bulletin, January, 1894.

of small, apparently trivial factors. Possibly it is sometimes owing to the inherent unconscious vanity of most people to desire to make the object of their research fit their already-formed conclusions. The truth of a paragraph that I saw not long since recurs to me and seems to have a special applicability to the discussion of medical subjects. It was that "the position of a genuine searcher for truth must be one of a sort of agnosticism, and he must be actuated by a constant supersensitiveness for truth."

There are many cases of consumption which are purely pulmonary in which there can be no doubt that a rest-cure might work the happiest results. They are cases in which the bankrupt condition has not generally affected the body. By reforming the corrupt official, the rest of the body being in accord with the physician, we have a restoration to health.

But, unfortunately, we have many cases in which you cannot put your finger on any one part and say, "it is here the trouble is," for the whole body of officials and employees are constitutionally corrupt, and in place of good coin are constantly turning over imperfect and counterfeit material. The patient is not only suffering physiological starvation, but is constantly being poisoned by the very food he takes in to nourish him. This condition might be called one of suboxidation, and is a condition that is not sufficiently considered in treatises on tubercular phthisis. In many cases we have tubercle in almost every tissue of the body, lungs, bowels, kidneys, liver, skin. In feeding these cases we have to take this condition of suboxidation into consideration. We have not only to build up new tissue to supply the waste, but we have to supply the elements necessary to oxidize and carry off the double waste going on as well from the broken-down tissues as from the excess of food which is not "burned up" as it should be in a normal condition. The latter element, of course, can be more or less governed by regulation of the food supply, but whether entirely or not is a very doubtful question, and it is probable that there is always a very variable factor of imperfectly digested food to take into consideration. This is a point that is very much neglected in general practice.

Every one is familiar with the fact that the food we take within us contains the elements of death as well as of life. That which is innocent and life-giving in one case is deadly poisonous in another because of functional or organic incapacity of the vital tissues. There is one food, however, that can, it seems, be taken in almost immeasurable quantities. This is oxygen, and is the element required to relieve the condition of suboxidation.

How, it may be asked, are we going to increase the consumption of oxygen or produce a forced consumption of that element? By exercise in the open air. The law of a living, healthy human animal is action; and any attempt to reduce him to a plant life or vegetative existence is followed by a retrograded condition, physically and mentally. There are many persons to whom a very moderate amount of confinement means degenerative changes and death. This may more especially be the case with persons who have always been in the habit of leading an active life.

How many unfortunate cases have we seen who were rapidly wasting away in the possession of all the luxuries that wealth and friends can give them.

How many others have we seen who, on account of circumstances of poverty, necessity or ambition, have been compelled to keep at their posts and who have worked and suffered half a lifetime before giving up to the destroyer.

It is argued by the advocates of a rest-cure that the vital energies should be conserved toward the building up of new tissues to take the place of the degenerated and diseased tissue. But this is taking it for granted that the emunctories will do all of their work with the patient in a quiescent state. Our experience is that the emunctories are sadly at fault here, and without a discreet amount of exercise are very apt to be deficient. Indeed, it seems essential that in order to build up healthy tissue one must tear down tissue; and the more rapidly, within certain limits, this change of waste and repair goes on, the better. But it is necessary to the success of this theory that the waste and repair should take place in presence of a free supply of oxygen, so that the tissue that may be laid up is stable and of high vitality and the waste that is removed shall be carried off without development of by-products.

This brings us to the kind of exercise

recommended, which should be that which will be productive of mild stimulation of all the tissues of the body without undue fatigue, without over-production of animal heat, and which should take place in an atmosphere containing a free supply of oxygen.

What will give this? Walking or the judicious use of the bicycle, *and nothing else!* There is no form of horseback or carriage exercise that will take the place of these. Most all other kinds of outdoor exercise are too violent, and no kind of indoor exercise is suitable on account of the absence of pure air.

There is another point that is attained by this treatment, which is very important: It stimulates the peripheral circulation and nicely regulates the heat centers, preserving an even temperature—two things which are very much in default in many chronic cases. It is well known that in many cases of constitutional phthisis there is frequently a tendency to irregularities of circulation, with internal congestions and great disturbance of the heat centers. Everything, then, which interferes with the action of those centers, such as quiescent conditions in the open air, especially during damp, cool weather, favors congestion, and every congestion, even though of very short duration, intensifies any local trouble wherever it may be situated in the body. Hence can be seen the ill effects of carriage-riding in any but the warmest weather. It is astonishing, notwithstanding the fact that cool, dry weather is the best for consumptives, how much apparently unfavorable weather can be endured, provided a person is thoroughly protected by suitable dress and mild exercise.

Though I do not pretend to be much of a believer in hypnotism, mind-cures, etc., I must say that I think the will may have much to do in conquering these wasting diseases, especially when coupled with the most enlightened treatment that can be had.

Just here I would like to introduce a very apt sketch to illustrate this power of resolution. In the "Memoirs of Vidocq, Chief of the French Police," a little book which I once picked up, there is a story of a soldier who, being stricken with consumption, lay in his tent paralyzed with fear and hopelessness. In his agony he betakes himself to the tent of his commander and requests a discharge, giving as motive his physical condition. The captain speaks roughly to him, tells him that the only medicine for his trouble is a bullet, and refuses him his discharge. Wandering around in a dazed condition one day during the occurrence of a severe military engagement, he has an opportunity to distinguish himself by hurling away a lighted bomb which was about to explode, thereby saving the lives of a number of his companions. A few days afterward again at the risk of his life he rescues a woman and her child from a burning building, and from that day, by application and personal bravery, was repeatedly promoted until he became general of a division. The narrator prefaces his remarks with a personal description of the man, which represents him not, as one might suppose, lusty and well favored, but looking, as I have seen many a man look who had lived long and well, "a death's-head surmounting a bag of bones!"

It is a question with us, even if it were possible, whether it is well to lay on much flesh in a well-marked case of phthisis. For that which is formed under forced feeding without much exercise is of a vitality lower than in a normal, healthy person.

This is particularly the case in hereditary examples. The result may be that if at any time subsequently, as result of hardship, misfortune or mental overwork, the subject may acquire a return of the disease, on account of the lower vitality of the new-formed tissues they will rapidly waste, using up in their combustion the life-giving oxygen which should be devoted to supplying the vital forces. The result is that we have immediately the condition of suboxidation spoken of above, and the patient, unless skillfully treated, is likely to be drowned in his own excretions.

We believe that the majority of phthisical cases may be saved to long life, if not cured, if we can have the most favorable environment and treatment. The difficulty is that it is almost impossible to regulate the treatment and environments of patients outside of special hospitals. With proper food, times of eating, etc., suitable clothing, attention to all the most minute particulars of sleeping-rooms, heating, bedclothes, living-rooms, bath-rooms, bathing, closets, etc., then with proper

exercise and rest and some interesting, easy, but not too engrossing or exacting pursuit, the lives of consumptives might be made an Eden of perennial joy.

There is one thing that cannot be too much insisted upon. Consumptives ought never to be *impecunious*, but ought either to be the sons or daughters of wealthy parents or ought to inherit or acquire wealth in some manner. For this reason: that for years after an apparent restoration to a fair degree of health the consumptive ought not to be subject to the ordinary exactions and sacrifices of making a living in this busy world. For it is always certain, if they are so subject, that a day may come when a little extra strain or exposure will start them on the down path again and bring back all the original symptoms.

A few remarks might with advantage be added on the subject of feeding in consumptive cases who are pursuing an active outdoor life.

It is interesting to note that imperfect starch digestion is one of the peculiarities in the disease, and this notwithstanding the fact that a certain amount of starch is very necessary to the production of a healthy state of the body.

The proof of the above is evidenced by the natural repugnance which many consumptives have for starchy food, and that when it is ingested in any great quantity the result is almost always either a good deal of diarrhœal trouble or else flatus, and foul gases are expelled by the rectum.

In this connection we submit that these gases, which are generally supposed to be pathological in the sense that they should be opposed by antiseptic medication, are, in our opinion, conservative; that they are by-products which by their generation prevent the formation of more injurious waste products, and by their expulsion prevent diarrhœa and intestinal irritation; that when formed the patient should be encouraged in the habit of getting rid of them per anum.

One of the most promising signs, then, of convalescence in consumptive cases is the ability to digest starchy food. The long train of symptoms, such as cold extremities, irregular heat production and the tendency to local congestive conditions, is at once alleviated and a sense of well-being never before experienced is obtained.

An individual may exist for a long time on a course of meats and nitrogenous foods, but that treatment is only preliminary to the addition of starch food to the diet, which must take place to complete the cure. This is sometimes attempted by the substitution of alcohol, one of the congeners of starch, but it is a feeble and often dangerous staff and as often breaks the patient or fails utterly. With alcohol it is often a question of dying of consumption or of delirium tremens, and the patient must choose between the two.

Oxygen and outdoor exercise are the necessary adjuncts to starch digestion, and it is interesting to find, with the use of these, what an amount of starchy food can finally come to be disposed of by the digestive tract. One also will find almost invariably that whenever circumstances render outdoor exercise temporarily inconvenient or impossible, the starchy food must be immediately cut down or one will have as a result increased flatus or diarrhœa.

Another point of interest, too, is the peculiar idiosyncrasy of some patients as to the variety of starchy food which is taken, the manner of cooking, etc. As a general rule white potatoes, baked and served hot and fresh from the oven, are better assimilated than any other form of starch unless it be wheat bread. The same holds good for sweet potatoes, and one great desideratum is that they should always be dry—not water-soaked. Some patients can eat chestnuts, boiled or roasted, when all other starches are repugnant and indigestible, and absurd as it may seem, I have seen one patient who in the early chestnut season could devour quantities of fresh raw chestnuts almost *ad libitum*, when at the same time his lower intestinal tract was in such an ulcerated condition that specks of blood were passed with the stools.

ACUTE INFLAMMATION OF THE MIDDLE EAR, TERMINATING IN [PURULENT PERIPHLEBITIS OF THE LATERAL SINUS AND THROMBOSIS—OPERATION—RECOVERY.*

ALBERT H. BUCK, M.D., NEW YORK.

The patient, a man of strong physique, about fifty-four years of age, consulted me on January 29, 1894, for the relief of pain in the left ear. For several days previously he had been suffering from a "cold in the head," and on the preceding day he had taken a sleigh-ride; but he had not been conscious of having experienced at the time any chilling of the body. The pain had first been felt early in the morning of the day following that on which he took the sleigh-ride—that is, only a few hours before he came to my office. I examined the ear and found the membrana tympani, especially the upper half, markedly hyperæmic. There was also a decidedly congested and swollen condition of the naso-pharyngeal mucous membrane. No secretion had as yet accumulated in the drum cavity. An application of a fifteen-grain silver nitrate solution was made to the vault of the pharynx, and hot poulticing and rest in bed were prescribed.

On the following day I visited the patient at his home and found that he had experienced very little if any relief from the pain in the ear. The appearance of the drum membrane showed that the drum cavity was already full of secretion, and that the inflammation was increasing in violence despite the hot and moist applications. I accordingly made a long, crescent-shaped incision in the posterior half of the membrane, affording a free outlet to the pent-up blood-stained serum, and I ordered a continuance of the poulticing and the free use of the hot-water douche.

The paracentesis afforded a measurable degree of relief, but only for a short time. On February 3d, 5th, 7th and 10th it was found necessary, on account of the rapidity with which the opening healed and on account of the return of pain whenever the opening ceased to be of fairly large size, to repeat the paracentesis. Soon after the first operation the discharge became purulent in character and quite abundant. On February 11th or 12th there was a slight tenderness on pressure behind the ear, and accordingly three leeches were applied to this region.

On the 14th, as the leeches had afforded only temporary relief, a Wilde's incision was made; and on the following day a seton was established at this point. A very broad, curved needle (made specially for the purpose), with cutting edges and armed with six or eight threads of coarse silk, was introduced at the bottom of the Wilde's incision and pushed out backward through the skin at a spot about one inch distant from the point where it had entered.

The discharge from this artificial sinus, kept in an irritated condition by the presence of the mass of silk, failed to exert any marked impression upon the amount of discharge from the middle ear or upon the subjective pain experienced by the patient. After the seton had been in place for four or five days, the patient had a sharp chill which lasted for a few minutes, but was not followed by any appreciable rise in temperature. (The patient's body temperature was tested nearly every day and sometimes twice a day, but it was always found to be either normal or at most two-tenths or three-tenths of a degree above the normal.) At the time I felt confident that this chill was due to the imprisonment of pus in the seton channel; for when I examined the parts one or two hours afterward I found both orifices practically closed by the drying up and caking of the discharge

*Read before the American Otological Society, 1894.

at these points, and even in the light of later developments I am still disposed to look upon this as the correct explanation.

On February 21st Dr. Herman Knapp saw the patient with me in consultation. The pain had not been materially diminished by any of the measures which I had instituted—repeated paracenteses, hot poulticing and frequent douching of the external auditory canal, the application of leeches to the mastoid region, a Wilde's incision followed by the introduction of a seton, an occasional dose of calomel, the daily employment of the Carlsbad Sprudel salts, etc.—and it was becoming more distinctly hemicranial in character. I therefore felt that the time had arrived when it would be wise to establish a free outlet from the mastoid antrum through the mass of bone lying outside of it. On this particular day, however, the patient felt decidedly better than he had felt for several days previously, and we accordingly agreed to postpone, at least for the moment, the consideration of the question of operative interference. It was decided, however, to remove the seton, for it was apparently accomplishing no good purpose, yet at the same time it was preventing us from estimating correctly, by aid of such signs as tenderness on pressure, swelling, etc., of the skin, how the underlying mastoid inflammation was behaving. Dr. Knapp's examination of the patient's left eye with the ophthalmoscope gave a negative result.

On the following day (February 22d) the patient once more complained of decided pain in and around the ear; and as the opening in the drum membrane had by this time again become insufficiently large for free drainage of the inflamed middle ear, I excised a small portion of it by first making a flap (with its base below) and then snaring off its upper free extremity. The incision which marked the posterior limit of this flap approached very closely to the curved line corresponding to the insertion of the membrana tympani in the sulcus tympanicus, and as the knife passed through the thickened tissues of the membrane there was a sudden escape of thick creamy pus quite different from the muco-purulent secretion escaping from the old opening in the membrane. By further manipulations I succeeded in dislodging through the opening a core-like mass as large as a No. 3 shot. The introduction of a bent middle-ear probe revealed the fact that the posterior wall of the cavity from which this creamy pus and this core-like mass of broken-down tissue had been evacuated was bone denuded of its covering of mucous membrane. In other words, I had accidentally evacuated a separate collection of pus located at the posterior end of the tympanic cavity between the surface of the bone and the mucous membrane (periosteum), just beneath the entrance to the mastoid antrum. In the natural state the bone at this point is somewhat rough and irregular. From the sense of touch alone, therefore, I could draw no safe conclusion as to its condition. There could be no doubt, however, about its being in a state of inflammation.

The relief afforded by this operation was but very little, if at all, greater than that afforded by my previous simple paracenteses.

On March 1st Dr. Knapp again saw the patient with me, and it was decided to cut down to the antrum. The operation was performed in the usual manner. No well-marked pneumatic cells were encountered until I had chiseled away the bone to a depth of nearly half an inch. These cells were all found to be filled with granulation tissue, and at all points the bone substance was found to be in a condition of marked hyperæmia. Close to the antrum, however, it was found to be of a bluish-black color and softened. No pus was encountered until the antrum was reached, and then only a barely recognizable amount. Every portion of the wound, the antrum and the tympanic cavity proper was thoroughly irrigated with a 1:4,000 bichloride solution—the fluid escaping freely from the middle ear into the external auditory canal. No sutures were employed, and the wound was dressed with iodoform gauze.

From March 1st to the 16th nothing worthy of special note occurred. The operation caused the pain to almost disappear at first, but gradually it returned and steadily increased up to the date last mentioned. Then, in the belief that there might perhaps be some obstruction to the free escape of pus, I reopened the wound freely and with a Volkmann's spoon cleared away all the granulation tissue which had formed in the antrum and in the excavation made in the bone out-

side of the antrum. This procedure, however, afforded only temporary relief. From time to time during the following three weeks I tried different kinds of drainage-tubes and contrivances, in the hope of securing complete freedom from pressure upon the mass of escaping pus; for whenever I succeeded in accomplishing this, even for a short time, I observed that the patient experienced comparative freedom from pain. But the discharge was abundant and granulation tissue repeatedly blocked the openings in the drainage-tube, thus reëstablishing the condition of pressure which was so undesirable. It was during this period that the patient had the second and last chill that he experienced during the entire illness. The drainage-tube at the time was completely blocked, and there was an appreciable increase in tension of the skin surrounding the outlet. I am unable to state whether this second chill was or was not associated with a rise in the body temperature.

Toward the end of the period now under consideration there was a noticeable increase in the redness and swelling of the integuments covering the lower and posterior part of the mastoid process, and the lateral movements of the head caused some distress. But there was no tenderness along the side of the neck, and the tenderness over the tip and posterior aspect of the mastoid bone was but little, if at all, greater than one usually finds in the vicinity of a still open mastoid wound. The discharge, however, was more copious than it should be from such a wound, and I made up my mind that there must be a center of active osteitis in the lower part of the mastoid bone. Accordingly, on April 9th the patient was put under the influence of chloroform, and a considerable portion of the lower part of the mastoid process was removed by chiseling. No center of pus was found, but everywhere the bone appeared to be in a markedly hyperæmic state.

During the week following this operation the patient's condition steadily grew worse in the following respects: The movements of the head became more painful, there began to be an appreciable degree of tenderness below the mastoid process, and the swelling, tenderness and pain in the region lying between the mastoid bone and the occiput increased to an appreciable degree. Then, besides, he found that he could read for only a short time, on account of the pain which it produced in the left eye. On the other hand, the body temperature did not rise above 99.4° F., the pulse-rate did not exceed 82 beats to the minute, and the patient continued to take his food with relish. The symptoms just enumerated, however, satisfied me that the inflammation was extending in a backward and perhaps inward direction, and that a bolder search for some center of pus should be made in these directions. This conclusion was still further strengthened by my finding, on April 13th, that pus from some new source, situated below the artificial opening in the bone, was burrowing down the side of the neck in front of the sterno-cleido-mastoid muscle.

On April 14th the patient was brought under the influence of chloroform, and I proceeded to chisel away the outer and posterior surface of the mastoid process. At all points the bone was found to be markedly hyperæmic, but no pus or appreciable softening of the bone substance was found until the immediate wall of the channel for the lateral sinus (sigmoid groove) was reached. At this point, situated at a depth of fully half an inch from the outer surface of the mastoid process, the bone seemed to have undergone a certain degree of softening, and odorless, creamy pus welled up from this cavity as soon as the chisel cut through the surrounding softened wall of bone. By means partly of the chisel and partly of a medium-sized Volkmann's spoon I enlarged the opening until it measurep about three-eighths of an inch in diameter. The outer wall of the exposed vein was found to be granulating, but not softened, so far as I could judge by pressure with the probe. The absence of all tension warranted the belief that the vein was thrombosed at this point. So far as I could judge, the pus surrounding the vein came partly from some point higher up and partly from below. I fully expected to discover roughened bone or the opening of a fistula at some point along the anterior aspect of the sigmoid groove, but my probe revealed no such point.

The situation of affairs, as brought to light more fully by this operation, made me feel that I could no longer do full

justice to the case; that in the further search for centers of pus regions would have to be laid bare with which I did not feel myself to be sufficiently familiar; and that, therefore, a general surgeon should be summoned. Accordingly Dr. Frederick Lange was invited to take charge. The patient was once more anæsthetized (April 16th), and Dr. Lange proceeded first to expose thoroughly the downward track of the pus along the jugular vein. Then he removed, by chiseling and by the use of the rongeur forceps, all that remained of the mastoid process; thus laying bare the jugular vein from its situation in the sigmoid groove down to a point perhaps one inch below the level of the tip of the mastoid process. All of the jugular vein thus exposed to view was evidently in a thrombosed condition, as its walls showed no changes in tension when firm pressure was made upon the side of the neck lower down or when the patient coughed. Dr. Lange also removed, in an upward direction, enough of the squamous portion of the temporal bone, where it forms the outer wall of the vertical part of the lateral sinus, to give him free access to any collection of pus that might exist in this part of the cranial cavity. No such collection, however, was found. Then, finally, he worked his way cautiously downward and inward until he had exposed the styloid process, the trunk of the facial nerve as it emerges from the stylo-mastoid foramen, and the region beneath the foramen lacerum. The probe was passed through this opening into the cranial cavity, but no collection of pus was found. All this work, I scarcely need to state, was performed under constant aseptic and antiseptic precautions. After the operation was completed a drainage-tube was laid in the wound, with its inner end resting against the deepest part of the excavation, and iodoform gauze was packed around it. A few turns of a bichloride gauze bandage served to keep the dressings well in place.

On the day following the operation the temperature rose to 100.4° F., and then gradually fell, during the course of the following week, to normal. The pain in the left eye brought on by reading gradually disappeared, and with it the slight alterations observed by Dr. Knapp, shortly after the operation, in the fundus of the eye. At the end of three weeks the patient was allowed to leave his bed, and at the present time of writing (May 27th) the wound has progressed so far toward healing that its complete cicatrization may be looked for in the course of the next two or three weeks. No drawbacks of any kind have occurred during this period.

The discharge from the middle ear, by way of the external auditory canal, ceased on the third or fourth day after the first operation upon the mastoid process; but on two or three subsequent occasions it returned for brief periods of time. It was not clear to what these slight relapses were due; but it is probable that some interference with the drainage from the antrum, by way of the outside wound, caused sufficient back pressure to reopen the perforation in the membrana tympani.

Throughout almost the entire attack the hearing in the affected ear remained fairly good, and soon after the last operation it returned to a practically normal condition.

Comments.—The most striking feature in this case, as it seems to me, is to be found in the fact that the disease began, almost at the very start, as an osteitis. There was, it is true, the usual antecedent naso-pharyngeal inflammation, and this inflammation spread in the usual manner to the mucous membrane of the middle ear. But the course which it pursued after it had reached the latter cavity was certainly very different from that which we are accustomed to see in the vast majority of cases. I have often said to myself, and have perhaps expressed the view to others, that if an acute inflammation of the middle ear (not associated with diphtheria, measles, scarlet fever, smallpox or typhoid fever) could be subjected to suitable treatment within the first twenty-four hours, it would never progress so far as to seriously involve the neighboring mastoid process. In the present instance the patient presented himself within a few hours of the time when he felt the first twinges of pain in the ear. Simple antiphlogistic measures were employed immediately, and then, as soon as any secretion had accumulated in the drum cavity—that is, at the end of twenty-four hours—a very free opening was made in the drum membrane in order that intratympanic pressure—the factor which is believed to play perhaps the most impor-

tant part in the aggravation and further spread of an acute middle-ear inflammation—might be quickly done away with. But it is evident that in the present instance only a very transient beneficial effect was produced by this and the succeeding efforts to reduce intra-tympanic pressure to a minimum, or by the other antiphlogistic measures employed. The most plausible explanation of this lack of success in arresting the inflammation is to be found, I believe, in the assumption —which is strengthened by the facts revealed in the latter course of the disease—that already at this early stage the inflammation of the adjacent bone, particularly that portion which lies near the posterior end of the tympanum and around the antrum, had gathered considerable headway. It is not unlikely, furthermore, that there may have been certain anatomical peculiarities which rendered this mastoid bone more than ordinarily liable to participate in any inflammation that might develop in the contiguous tympanic mucous membrane. As favoring this view, I may mention the facts that seventeen years ago I operated upon this same patient's right mastoid process, and that one of the most troublesome features in the case was an obstinate tendency to the formation of firm granulation tissue around a small spot of bone caries situated at the posterior end of the tympanum, just beneath the entrance to the antrum.

The absence of fever and of chills (the two mentioned in the history of the case were, I believe, due to special conditions) may also be noted as something unusual. The absence of these symptoms probably indicated that up to the time of my last operation the inflammation had not gone much beyond the stage of periphlebitis of the lateral sinus, and that whatever actual phlebitis existed must have been of a mild, non-infective character, simply active enough to create a thrombus.

The present case and others of a more or less similar nature that are to be found recorded in medical literature justify the establishment of a rule something like the following: The persistence of deep-seated pain behind the mastoid process after the antrum has been opened into and thoroughly drained, is sufficient warrant for making an opening into the sigmoid groove for the lateral sinus; and it is not advisable to wait until the patient has chills, or until the body temperature rises to an appreciable degree, before resorting to operative interference in this direction. If we wait for the corroborative evidence furnished by the symptoms last named, we shall lose lives that might otherwise be saved.

CHRONIC TYMPANIC VERTIGO—ITS RELIEF BY SURGICAL LIBERATION OF THE STAPES.*

CHARLES HENRY BURNETT, M.D., PHILADELPHIA.

Inspection of the mechanism of the conductors of sound reveals an arrangement peculiarly well adapted to carry the stapes inward toward the labyrinth. Such inward excursion of the ossicles is in fact made in every normal ear with every wave of sound falling on it. That a limit to this inward motion of the stapes is desirable is shown by the presence of the stapedius muscle, the antagonist of the tensor tympani. The latter muscle draws the malleus inward and aids it to force the incus and mediately the stapes inward. If abnormal retraction in the conductors ensues from any cause, the stapes, being the weakest of the conductors of sound, is forced unduly into the oval window. Excessive pressure is thus exercised upon the labyrinth fluid, the motor filaments of the auditory nerve are irritated and vertigo is the result. If such morbid retraction in the conductors of sound is of frequent and prolonged occurrence, as in chronic catarrh of the middle ear, chronic vertigo may be added to the tinnitus and deafness already present.

*Read by title before the American Otological Society, 1894.

For such phenomena of disturbed equilibration in chronic catarrh of the middle ear (sclerosis), I have suggested the name of chronic tympanic vertigo. The term Ménière's has been applied usually to this affection. But this is a misnomer, for Ménière's disease means a disease of the labyrinth and not a diseaseof the middle ear.

Chronic tympanic vertigo usually occurs in an ear which has been for some time previous the seat of tinnitus and deafness from a chronic catarrhal process in the drum cavity. The nares and naso-pharynx usually show by this time no disease, though the catarrhal process may have started there. The membrana tympani will be found markedly and continuously retracted, and the stapes therefore unduly pressed into the oval window and held there by the overpowering weight and force of the malleus and incus.

A characteristic feature of chronic tympanic vertigo is its paroxysmal occurrence. This is due to the fact that the labyrinth tolerates to some extent the chronic pressure of the stapes; but a change in the circulation in the middle ear, in varying conditions of health of the patient, brings about increased retraction in the already retracted ossicles, undue inward pressure of the stapes ensues, and a paroxysm of vertigo of longer or shorter duration sets in. The same phenomena appear when the quantity of lymph in the labyrinth is increased in a general afflux of lymph to the head, in a case where the labyrinth space is compromised by a chronically impacted stapes. The paroxysmal nature of chronic tympanic vertigo distinguishes it from the vertigo from a tumor in or near the auditory nerve, which is always constant, though it may be slight. Retention of consciousness, even in the worst cases, where the patients reel and fall, serves to distinguish tympanic vertigo from epilepsy and apoplexy—though it is unfortunately too often mistaken for these maladies.

The only way to relieve chronic tympanic vertigo is to liberate the stapes. This is best accomplished by elimination of the incus from the retracted chain of ossicles. Thus the power of the retracted lever is overcome, and the stapedius, relieved of its forceful antagonist, the tensor tympani, lends assistance in drawing the stapes from the oval window, and the morbidly impacted bonelet is liberated.

That morbid retraction of the conductors of sound and impaction of the stapes are the cause of chronic tympanic vertigo, and that this disease is relievable by removal of the incus, is amply demonstrated by the following cases, which are the latest in a series of 20 similar ones.

Case XVII (in a series of 20).—Mrs. K , aged forty-six, of Maryland, consulted me December, 1893. The patient had an attack of acute catarrh in the head over three years before the date of her first visit to me. Soon after the catarrh of the nares and naso-pharynx, tinnitus and dullness of hearing were observed in the left ear, and fifteen months later vertigo was felt, and attributed by the patient to the discomfort in her ear. She felt more or less vertigo all the time, became depressed in spirits and suffered from more frequent and severe paroxysms of tympanic vertigo. These attacks numbered at least two or three a month, and made the patient unwilling to leave the house alone. Finally, after much treatment for nervous prostration, but none for her ear, the seat of the disease, the case was taken to Dr. S. Weir Mitchell, who, recognizing the true nature of the disease, referred the sufferer to me.

Otoscopic examination revealed a thickened membrana on the left side; incus not visible through the membrane; hearing much reduced; nares normal. Chronic tympanic vertigo, due to retraction of the ossicles and undue impaction of the stapes in the oval window, was diagnosticated, and the removal of the incus advised in order to liberate the stapes.

Consequently, though the patient was in a very nervous condition, she was etherized January 23, 1894, and the incus removed after myringotomy in the upper posterior quadrant of the membrana.

January 24th. The patient can walk decidedly better and is very cheerful. Hearing unimproved and tinnitus unchanged. The patient goes home to-day.

Unfortunately this patient took cold on her way home and seemed worse in every way for some time. By March 15th, however, when she came to see me, I found that the tinnitus was much less, there had been no paroxysms of intense vertigo for some weeks, and, in fact, the vertiginous tendency seemed permanently banished. The patient looked five years younger and

was very active on her feet, being no longer in fear of vertigo and falling. Thus the object of the operation had been attained.

CASE XVIII.—Mr. W. P., of Philadelphia, aged thirty-four, a clerk, consulted me January 29, 1894, for tinnitus in the right ear, more or less paroxysmal in nature and culminating at times in vertigo.

Otoscopic examination of the right membrana revealed that the membrane was perforated below the manubrium, and through the heart-shaped opening the mucous membrane beyond gave evidence of having been the seat of chronic purulency. The rest of the membrana was thick and rigid, seemingly attached to the incus or its remnant and lying against and pushing inward the stapes; which bone, however, was not visible.

The deafness in this ear was profound. For two months previous the tinnitus had been increasing in the right ear and the patient had experienced an unaccountable tendency to vertigo, which he supposed to be due to stomachic derangement. The exacerbations of vertigo became more frequent and more intense until the patient was afraid to walk in the street alone, and at last in February he ceased to go to his business on account of disability induced by the tinnitus and tympanic vertigo.

It now became manifest that these disagreeable symptoms in the right ear were due to impaction of the stapes in the oval window. It was therefore proposed to liberate the stapes by cutting into the thickened upper posterior quadrant of the membrana tympani and then removing the incus. The patient was etherized March 2, 1894, and a wide incision made in the thick membrana. A piece of the long shaft of the incus (the only vestige of this bonelet) was found imbedded in the thickened membrana and removed. This exposed and liberated the stapes, which was found to be very movable. Owing to the upward shrinking of the membrana, as I have observed in other cases of loss of the incus from chronic suppuration, the stapes appeared relatively very low, nearly on a line with the lower end of the manubrium. The stapes is still plainly visible and readily movable. After the operation the vertiginous tendency diminished. In a week the patient was able to walk alone in the street, and he returned to business. The tinnitus grew less, but not as rapidly as the vertigo. The hearing was not improved.

In 7 other cases of tympanotomy and removal of the incus I have found at the time of the operation mobility of the stapes, notwithstanding the usual symptoms of chronic catarrh of the middle ear. Tinnitus and vertigo have been relieved in all of these, but the deafness has remained unchanged, notwithstanding the persistent mobility of the stirrup. This I believe to be due to the fact that in these cases the proximal nerve structures in the percipient organ—those nearest to the vascular structures of the middle ear and most readily affected by the catarrhal disease in the tympanum—are atrophied, while the distal nerve-tissues in the semicircular canals—those most remote from the chronic vascular changes in the drum cavity—retain their functions and are impressed by impaction of the stapes.

CASE XIX.—Miss H. O., of New York, forty-seven years of age, had suffered from chronic catarrhal deafness and tinnitus for several years. Finally chronic tympanic vertigo had been developed. Otoscopic examination March 14, 1894, revealed a greatly retracted and thickened membrana tympani; incus not visible through the membrane; no hearing on this side. March 16th the patient was etherized and myringotomy in the upper posterior quadrant was performed. The incus-stapes connection could not be seen. The incus, however, was carefully disarticulated from the stapes by means or an incus hook-knife and its long shaft drawn into view. The incus was adherent in the attic, and when traction was made to remove the bone the long descending shaft broke off. The ear was then slightly stopped with boric-acid cotton. The patient went home in four days. No reaction occurred in the ear.

May 10, 1894. The patient called to see me and reported much less tinnitus and a greatly diminished tendency to vertigo.

CASE XX.—Mrs. C., of Philadelphia, aged forty-seven, consulted me regarding aural vertigo April 2, 1894. The patient stated that she had suffered from chronic catarrhal deafness and tinnitus in both ears for several years. Within four months the tinnitus in the right ear had greatly increased and was so intense at times as to cause dizziness and faintness.

Otoscopic examination revealed a thickened membrana, retracted and forming a very obtuse angle with the posterior wall of the auditory canal. The incus could not be seen through the membrana. Chronic tympanic vertigo from undue retraction and impaction of the stapes was diagnosticated, and the patient was advised to submit to removal of the incus, for which operation she had been, indeed, sent to me. Therefore on April 17, 1894, the patient was etherized and the incus, which was placed high in the attic, was removed with difficulty, because the manipulations in such a case must be excessively delicate and very slow for the sake of caution and gentleness.

The patient felt no relief of any kind for ten days; then the tinnitus diminished and there was much less tendency to vertigo.

The hearing in the left ear had by this time improved considerably; tuning-fork $\frac{4}{11}$, against nothing before the operation. She hears isolated words, too, much better—six inches before the operation; one to two feet now. The tongue is numb on top from irritation of the chorda tympani.

April 30th. Tinnitus very slight and no tendency to dizziness or vertigo. Hears conversation much better in the right ear.

May 7th. The patient continues free from vertigo, notwithstanding a severe cold. Perforation in the membrana has been closed a month.

TRANSLATIONS.

CATHETERISM OF ARTERIES.*

Severeanu, of Bucharest, Roumania (*Le Progrès Médicale*, August 11, 1894), remarks that it seems paradoxical that any one should find it necessary to introduce a sound into the lumen of an artery for any purpose whatever. Every one knows the frequency of gangrene due to arterial embolism which by obstructing the artery arrests the course of the blood and causes the death by default of nutrition of the parts supplied by this vessel. It is thus that are produced septic gangrenes in typhoid fever and petechial typhus, some of the gangrenes of old people and the gangrene of certain people (Turks) who have the habit of maintaining their limbs in flexion for a long time. In these different cases the embolus is due either to atheroma in old people, to a clot which separates from the heart (endocarditis), to a coagulation of the fibrin of the blood by germs or toxines not yet well defined (typhus, typhoid fever, pneumonia), or, finally, it may be produced by a vicious attitude of the members prolonged for a considerable time and frequently repeated. The clot formed, either in the heart or higher, is swept on by the current of blood until it arrives at a strait where the caliber of the artery is narrower than the volume of the clot, when it stops and plays the *rôle* of a cork. The terminal segment of the affected member is exposed to death if the lumen of the vessel is completely obstructed or if the important collateral branches do not reestablish the course of the blood. Generally the embolus is arrested at a point of arterial bifurcation. Thus it is most frequently observed at the level of the elbow-joint, where the humeral artery divides into two branches, the ulnar and radial, and more often still in the popliteal space, where the femoral artery divides into the anterior tibial and tibio-peroneal trunks; hence the frequency of gangrene of the hand and forearm and of the foot and leg. The greatest number of gangrenes observed by Severeanu have been in the foot. Once only has he observed it in the hand and forearm, and this in a woman with heart disease; in this case he amputated the forearm in its upper third. In the case of gangrene of the foot, in order to insure a good result he has always sacrificed a long segment of the member, carrying his incision up to the point where he could detect the pulsations

*Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M.D.

of the artery. In cases where he has not followed this rule he has had the mortification of seeing the flaps become gangrenous, necessitating a secondary amputation or a prolonged process of cicatrization. This has suggested to him the idea of opening by a sound the branches of bifurcation of the popliteal artery, which are found not to pulsate at the level of the third adductors. He employed this process for the first time upon a man of fifty or sixty years, upon whom he had operated for gangrene of the foot consecutive to a cardiac embolus. The artery pulsated only at a high level; the gangrene had invaded the leg and did not manifest a tendency to limit itself. Amputation being positively indicated, in order to have the best chances of success he determined to practice amputation of the leg at the point of election. During the entire operation there was very little hemorrhage, rather capillary than arterial. Rubber sounds (Nos. 1, 2, 3 of the Charrière caliber) were prepared in advance, rendered aseptic by means of alcohol and carbolic acid, and introduced throughout their length into the lumen of the arteries, and on being pushed in and out the blood commenced to flow by the side of the sound. Having withdrawn the sound, the blood current carried out several cylindric clots having the shape and caliber of the artery, and the current of the blood was reëstablished. The arteries being ligated, the capillary hemorrhage became more abundant and the tissues assumed a more lively color. Following this maneuver the flaps did not become gangrenous, and reunion by the first intention was secured. Since then he has in every instance in which he discovered obliterated arteries practiced catheterism of the vessels, and has always congratulated himself upon the result. Usually the sound enters completely into the lumen of the artery, but in some cases this is impossible on account of adhesions between the clot and arterial walls; the flaps will then partially or completely mortify.

RECENT GERMAN SURGERY OF GALL-STONES.*

Dr. H. Kehr, of Halberstadt (quoted in "Schmidt's Jahrbücher von Gesammten Medicin"), out of 77 cœliotomies for gall-stones, found the calculus more or less firmly fixed in the cystic duct in 26 cases. As the accepted process for their removal failed in 7 cases, he resolved upon a new (or at least unreported) procedure, namely, the direct excision of the stone from the cystic duct, with immediate suture of the wound in the duct. With this method he has had the best results. Formerly he employed the suture of the gall-bladder in the abdominal wound and waited for the pressure of bile from behind in conjunction with the diminishing swelling of the mucous membrane to force out the calculus. Now he resolves upon an immediate cystico-lithectomy if he is convinced that the stone will not be spontaneously discharged, if he feels that it is too large to pass through the contracted cystic duct, if the condition of the patient allows further operation, if the cystic duct can be freely exposed so as to render its accurate suture possible, if an immediate evacuation of the cystic duct is necessary for drainage of the biliary system.

Dr. Kehr reports a series of 68 operative attacks on biliary calculi, in addition to 25 previously reported. The cases are grouped as follows:

1. Cholecystostomy, 31; with 1 death from suppurative cholangitis antedating the operation.
2. Choledochotomy, 6; with 1 death from peritonitis due to perforation of the transverse colon, the suture of the duct having held.
3. Cœliotomy and loosening of adhesions about the ductus choledochus, 1.
4. Cystecotomy, 6.
5. Cholecystectomy, 5.
6. Cholecystendysis, 2; with 1 death from pneumonia, the suture of the gall-bladder being firm and there being no peritonitis.
7. Cœliotomy on account of mucous fistula, 2.
8. Exploratory cœliotomy, 3 (gastric carcinoma, 2; pancreatic carcinoma, 1).

*Translated by Dr. A. L. Benedict, Lecturer on Digestive Diseases, Dental Department University of Buffalo, for THE MEDICAL AND SURGICAL REPORTER.

9. Closure of biliary fistulæ, 4.

10. Opening of biliary abscesses in the abdominal wall, 2.

11. Reopening of closed biliary fistulæ, 6.

No deaths occurred except as noted. Of the 3 fatal cases only 1 was directly due to operation.

Kehr has arrived at the following conclusions:

1. Too few operations are performed for biliary calculi; early operation is important.

2. Many patients with gall-stones belong not to Carlsbad, but to the surgical clinic.

3. The public must be informed as to the danger of biliary lithiasis, and the physician must not delay a necessary operation.

4. The course of the sickness and the intensity of the symptoms often determine the necessity of an operation.

5. The urgency may be great, although icterus, enlargement of the liver and tumor of the gall-bladder are absent. The pains, too, need not be typical of hepatic colic.

6. With chronic stomach trouble, for instance, gastric dilatation, especially with so-called cramps of the stomach, the possibility of gall-stones and of hernia in the linea alba must be borne in mind. Many patients are treated for gastric ulcer when they have calculi.

7. Riedel's tongue-like projection is presented in many cases of dropsy of the gall-bladder. Not seldom there is a confusion with a floating kidney of the right side.

8. Biliary colic is often a consequence of an inflammation of the gall-bladder. The accompanying icterus depends on the swelling of the mucous membrane of the biliary passages.

9. Adhesions, particularly between the gall-bladder and the pylorus, occasion attacks similar to colic, even when the stone has long ago been discharged.

10. For the removal of stones from the gall-bladder, cholecystostomy is useful; if the operation is properly performed no fistula results.

11. Adhesions must be broken up so far as possible.

12. The ideal method, with its modifications, must be rejected.

13. Total extirpation is to be thought of only when there is serious involvement of the walls of the gall-bladder, as in carcinoma, ulceration, etc. It is not indicated by a stone lodged in the bladder. In the case of a small, shrunken organ, Riedel's or Lauenstein's procedure is not available and then cystectomy is indicated.

14. Calculi of the choledochus are to be removed by incision of the duct, as previously stated.

15. Calculi of the cystic duct must, under certain conditions, be removed by direct incision.

16. Operation is often less dangerous than medicinal treatment.

17. A return has never been seen by the author.

18. Operations for gall-stones must not be performed except in surgical institutes.

19. They should be undertaken only by one experienced in abdominal work.

Chloroform in Lead Colic.

Dr. F. MacFarlan, of New York City (*American Therapeutist*), remarks that he has had great success in the treatment of lead colic by the internal administration of chloroform. He gives ten drops every half-hour if required. The pain is speedily relieved by the drug. The other features of the treatment go on in the usual way, such as the use of potassium iodide and laxatives. The chloroform is decidedly more effective in relieving the pain than the morphia, as a trial of the two remedies will abundantly prove. The speedier relief also favors a quicker and more satisfactory recovery.

Relation of Tuberculin to the Blood Cells.

As the result of recent experiments, Dr. Maurel finds that tuberculin, in the doses in which it is already employed therapeutically, has no sensible effect upon either white or red blood cells. His experiments also show that human leucocytes are able to resist successfully the bacillus tuberculosis, and that it is only necessary to attenuate the bacillus to a slight degree to enable the leucocytes to destroy the microbe. The experimenter suggests that it is only necessary to discover some agent capable of doing this to cure one of the most dreadful maladies with which the human race is afflicted.—*N. O. EDITORIAL.

THE GENESIS OF SERUM THERAPY.

Although of necessity brief and summary in character, a review of the origin and development of the treatment and prevention of disease by establishing artificial immunity will be useful, not only because of the intense interest aroused by the present investigations in the so-called anti-toxin treatment of diphtheria, but because the subject affords an excellent illustration of the persistent efforts made to raise medicine to the level of an exact science.

In the history of certain infectious eruptive fevers — small-pox, scarlatina, measles, etc.—three peculiarities have been constantly observed (conditions of exposure to infection, etc., being equal): (1) a limited number of individuals are proof against infection, *i.e.*, are naturally immune owing to some unknown personal quality; (2) a limited number of individuals cannot acquire immunity even by repeated attacks of the disease; and (3) the vast majority of individuals, readily susceptible upon exposure to infection, secure permanent immunity from repeated attacks of the disease by surviving a first attack, *i.e.*, are artificially immune.

During the last quarter of the eighteenth century Jenner, perfectly familiar with these facts, while investigating small-pox observed that those whose occupation brought them in contact with cattle were liable to acquire an analogous disease (cow-pox), which ran a very mild course in the human subject and which protected against the dreaded small-pox as thoroughly as did an initial attack of that disease itself. The results deduced from Jenner's observations have been one of the greatest blessings to humanity. He demonstrated the practicability of attenuating or modifying the small-pox virus by passing it through lower animal economy, eliminating its deadlier characteristics and returning for use in the human economy what it might contain of the beneficent to afford protection against

the disease which generated it. However, he could offer no scientific explanation for the phenomena produced, nor was a satisfactory theory advanced for three-quarters of a century.

Meanwhile the discovery of microbic agency in the process of fermentation had been made, whence have sprung the alluring theories of germs and their relations to disease.

Twenty-five years ago Pasteur discovered that the bacilli of chicken-cholera when exposed to the air for considerable time lost somewhat of their virulence and did not prove so fatal in effect as when fresh. Moreover, that chickens when inoculated with such modified virus were protected against the more virulent forms of the disease. Another discovery credited to Pasteur is that the microbes of a disease which belongs exclusively to a certain class of animals, although by no means destroyed, can be very much modified and the virulence abated by being transplanted to animals of different species. Pasteur likewise discovered that there was some substance in the spinal nerve tissues of a dog affected with rabies which would produce a form of disease even more virulent than the original; that this substance or virus could be so manipulated as to produce an extremely mild form of the disease, and finally a process was developed by which the system of an animal could be so trained and reënforced as to be invulnerable to infection with the most virulent virus produced. That is, the toxic element of the disease could be made to provide its own specific anti-toxin.

There are three prominent theories to account for the manner by which inoculation secures immunity. The first, and the one on which the anti-toxin treatment of diphtheria has been principally developed, is the one advanced by Behring and Kitasato. It assumes that the inoculation of the chemical poisons secreted by microbes during growth brings about a condition of tolerance in the body inoculated so that eventually it is prepared to withstand not only the effects of enormous doses of the poison in question, but also those of the very microbes producing the poison. This immunity is presumed to be due to the formation of an anti-toxin in the blood.

The second theory is based on the assumption that the part of the body in which any given germ flourishes is rendered sterile after it has borne a crop, so that afterward germs may be introduced with impunity, as they cannot take root and spring up.

The third is the well-known "phagocyte theory" of Metchnikoff—that is, the cells of the body become habituated by the milder form of the disease and are thus seasoned to resist attack from the disease itself. They become veteran cells, and like veterans can take care of themselves. In fact, they acquire the knack of swallowing and digesting the invading microbes.

It will be observed that the first-mentioned theory, which is also the latest to be promulgated, introduces an element which amounts to a radical innovation. The older theories assumed the presence of a specific microörganism as the immediate casual factor in the production of the disease. These hypotheses became untenable for a variety of reasons; one insurmountable difficulty being the failure to identify the predicated specific microörganism whose presence was required to be more than hypothetical. In many of the otherwise typical infectious diseases the keenest researches with the microscope and culture-tube have utterly failed to demonstrate any bacteria that can be alleged specific with a degree of plausibility.

About five years ago Salmon and Smith, of the Bureau of Animal Industry of the United States Agricultural Department, discovered that the metabolic products of bacterial energy when separated from the microörganisms themselves would secure

to the inoculated organism the same immunity as would inoculation with a living culture of bacteria. In other words, it was made evident that the immunizing agent was chemical in nature.

Another advance was obtained when the fact was recognized that there was considerable bactericidal power inherent in the blood of a healthy organism, due to a solution in the blood-serum of certain complex albuminoid compounds.

Pursuing this line of investigation, Behring "established the fact that the blood and blood-serum of an individual which has been artificially rendered immune against a certain infectious disease may be transferred into another individual with the effect to render the latter also immune, no matter how susceptible this animal is to the disease in question" (Krieger). The immunizing agent is the so-called anti-toxin.

Further investigation showed not only that an individual inoculated with it was proof against the toxins of the original disease, but that in an unprotected individual already infected with the original disease inoculation with the anti-toxin would neutralize the preëxisting toxins and cure the animal.

On these two observations hang all the loss and the profits of serum therapy.

It must be borne in mind that this is the barest outline of the subject and is in no sense a critical discussion. The results obtained were secured upon lower animals under the controllable conditions of a special laboratory and at the hands of scientists devoted to a specific and limited subject. The observations may have been correctly noted, and at the same time the field of observation may prove entirely too limited to justify the deduction of general laws from the observations made. In any event, there is a wide chasm between the rabbit in the bacteriological laboratory and the human sufferer among the sons of men.

ABSTRACTS.

SCARLET FEVER, WITH ESPECIAL REFERENCE TO CONTAGION AND PROPHYLAXIS.

Dr. Holyoke (Boston *Med. and Surg. Jour.*) writes:

Scarlet fever in recent years seems to be of a milder type than it was when I began practice more than twenty years ago. Its death-rate in this State is very much less now than it was then. Such variations in type have long been observed, and it is not impossible that severe forms of the disease may again visit us, although it is to be hoped that the continued good work of the health authorities will prevent any very destructive epidemic in the future. Still, this malady, in some form, is always with us; and in large cities it would seem almost impossible to eradicate it, fostered as it is by crowding, filth, ignorance and selfishness.

Besides the oversight of the health officers, the most hopeful means of limiting such diseases should be the influence exerted by the attending physicians. It is not sufficient that the individual patient be successfully treated, but the health of the community should be considered, and thosein charge of such cases be taught how these diseases spread and the best attainable means of prevention.

So far as we know, the virus of scarlet fever is, in most instances, taken into the system with the inspired air; but a number of cases have been reported from drinking infected milk, and we may assume that it is possible for it to gain entrance through any absorbing surface with which it can come in contact.

We are more practically concerned, however, with the origin and mode of dissemination of the virus, in order that we may deal with it at its source. It may be assumed that it is given off from all the surfaces of the body of the scarlet-fever patient. The most productive source is the desquamating cuticle; and when this is thrown off in the dry state and the fine particles are floating in the air, it is in a condition most favorable for reception into the system. In the moist state, as given off from the internal surfaces, it may not be such an immediate cause of danger, but we must believe that forcible expiration can dislodge contagious particles from the air-passages, which, either in the form of spray or dried and pulverized sputum, may be virulent even at an early stage of the sickness. It is possible that the urine and feces, if not disinfected, may contaminate the sewage and become a remote cause of trouble.

The most important means of preventing the spread of scarlet fever is isolation of the patient and the avoidance of all means by which the germs may be conveyed away until after they are disinfected. It is believed that the virus is not carried far by the air alone, although apparent exceptions to this rule have been noted. It is usually conveyed by persons or materials that have been in the vicinity of or in actual contact with the patient.

It is probable that scarlet fever, in most cases, is not very contagious during the first day or two; and if patients are separated as soon as the rash appears, those previously exposed will commonly escape. After this, however, it is certainly contagious as long as desquamation is going on, and although this may in some cases cease in three or four weeks, it usually continues longer and sometimes more than ten weeks. As a routine practice I advise isolation for six weeks from the beginning of the sickness, but sometimes find this period too short.

Our greatest difficulty is to secure proper isolation, especially among the poorer classes. During the height of the illness children are easily restrained, but when convalescence begins and they beg for liberty, it is difficult to impress upon parents the duty of restraint in the interest of public health. Another source of danger is the use, during convalescence, of books and toys which are not afterward destroyed and which cannot be completely disinfected. There is evidently much carelessness in this particular.

I will now report a group of cases which may serve to illustrate some of the points just noticed. In the early part of the present year a number of cases of scarlet fever occurred in the home of the Boston Children's Friend Society, on Rutland Street. The home contained at that time about 70 children, of whom, as nearly as could be determined, 55 had never previously had the disease. The first case appeared on January 17, 1894; others followed, at first in rapid succession, then at intervals of more than three weeks, when on February 10th there were 22 sick. After this there was a period of quiet for about six weeks, when 2 others appeared, on March 27th and 31st; and finally another one on May 1st, making a total of 25 cases.

For a little while we were in doubt as to the origin of the trouble, but in a few days reached the only conclusion which seemed to give a reasonable explanation.

At Christmas some persons connected with one of the Sunday-schools in Newton Centre collected from their scholars a quantity of second-hand toys and picture books, which were presented to our home. According to the reports in the daily papers, scarlet fever was then prevalent in that town, so that it became necessary to close some of the schools. From recent inquiry it is learned that the increase of scarlet fever in the town of Newton, including Newton Centre, began in November, when more cases were reported than during any other of the five months of its prev alence. The toys and books, which filled a barrel, reached the home on Rutland Street on January 2d, and were distributed to the children about eight or ten days later; and within another week the sickness began.

I have not attempted to trace the previous ownership of the toys. There would be manifest difficulty in doing so. But the facts that they were contributed by many persons in an infected district and that a few days after their reception by the children the malady appeared, make a strong probability that some of them were infected with the germs of scarlet fever. As soon as the toys and books were suspected they were collected and destroyed.

As cases of the disease continued to appear long after the destruction of the toys, we naturally inquire whether the later cases resulted from the original cause or from contact with the sick. In support of the first of these views we must remember that the toys and books had been in possession of the children about ten days. They had been widely scattered, and probably sufficiently handled to disengage many of the germs. It was impossible to fumigate the whole house, and it was not attempted except by burning sulphur in the play-room where the toys were first distributed. Therefore it was necessary to wait for the slow process of ventilation to remove the virus, which the cold weather rendered more difficult.

As soon as the children were taken sick they were at once separated, and their bedding and clothing removed and disinfected. The rooms occupied by the sick and their attendants were in a remote part of the building, well situated to insure isolation; and, as far as possible, all communication was cut off from the rest of the house. The management was so careful and the separation so complete that I consider it impossible that any should have become infected from this source.

We may now inquire whether it is probable that the disease continued to spread from contact with those recently affected before they were removed. In order to throw what light I can on this matter it will be necessary to examine the cases more in detail.

The children were divided into two classes, the so called school-children, over five years of age, and the nursery children, 10 in number, all under five years. I may say that the school was within the building.

The disease began with 2 children on January 17th, 3 on the 19th and 3 on the 20th. These 8 cases occurred in the older or school children, and all were undoubtedly produced by the original cause. Then, at intervals, in the course of the next three weeks, 8 more of the older children were taken sick. How these were infected may be a doubtful question. Some of them might have resulted from contact with incipient cases of the sickness, but I am inclined to believe that the original cause was still acting.

All the remaining cases happened in the nursery. The nursery children had received none of the suspected toys, and after the disease entered the home they were kept closely in their rooms and not allowed communication with the other children. But there was one exception to this. On January 24th one of these small children was allowed to leave the nursery for a few hours and mingle with the older ones in the school-room. Four days later he was taken sick. Eight days afterward another one came down, and I may mention that this child was troubled with a cough. From three to five days after this 4 others became ill, and then there was a long period of rest.

Of the cases just mentioned we need not discuss the first, in which there had been communication with the school-children. The second, occurring eight days later, is of doubtful origin; but there can be little question that the next four, following the second at intervals of three to five days, were infected by it. This seems more reasonable from considering the fact that the second child had a cough sufficient to dislodge contagious particles from the throat.

Three more cases remain to be noticed. Two of these appeared late in March and had been joined about a week before by several convalescent children, one of whom was found to be desquamating, although seven weeks had elapsed since she was taken sick. The remaining case appeared on May 1st, and the only explanation I can give is the following: One of those who had been affected was a girl aged twelve, whose sickness was severe and followed by prolonged desquamation. This was evident for ten weeks, but at the end of seventy-four days she was given an antiseptic bath and set at liberty. Her hair was long and thick. On the day she left the sick-room she went into the nursery, where only two children remained who had not had the disease. She also combed her hair with the comb used by those children. The visit was repeated a day or two later, and six days after her first visit one of the nursery children became sick.

Of the group of cases here reported the greater number may be regarded as due to circumstances largely beyond our control, but the last three could have been prevented by exercising more caution, although it may be said that the children who carried the infection were examined

before leaving the sick-room by a prudent and experienced person. These cases, however, emphasize the need of careful supervision of convalescents and tend to confirm the belief that many instances of scarlet fever result from neglect of this precaution or inability to carry it out.

In the way of prophylactic treatment many internal remedies have been recommended, both to the well, to prevent the development of the disease, and to the sick to prevent its spread. The most of these are such as have an antiseptic effect; and although we may be doubtful of their prophylactic influence on the general system, there can be little question that some of them have a very favorable effect on the mouth and fauces of the scarlet-fever patient, and probably render the secretions of those parts less virulent. Of those that may be classed as mildly antiseptic I still use, in most cases, the old mixture containing chlorate of potash and tincture of chloride of iron in small and frequent doses.

Since the most fruitful source of the germs is the desquamating cuticle, it is evident that the proper management of the skin is the most important part of the prophylactic treatment.

About twenty-five years ago Dr. Budd, of Bristol, England, reported excellent results from the application of olive oil as an aid to isolation. He usually combined a little camphor with the oil, and the application was made freely and often and continued until the patient was "well enough to take a warm bath." Then he was well scrubbed with antiseptic soap and water every other day until four baths had been taken, when the disinfection of the skin was regarded as complete.

Since that time most of the writers whose works I have examined mention the use of oil or ointments, either plain or containing antiseptics, but not all of them insist upon this measure as a matter of much importance; and as far as my observation extends, I do not think this method of treatment is used as commonly as its merits deserve.

Since the beginning of my practice I have always used olive oil as a remedial agent during the height of the sickness; but for some years past I have ordered it very freely throughout the whole period of illness and until desquamation has ceased, for the purpose of preventing the escape of the scales bearing the germs. There may be some advantage from combining antiseptics with it or from using thicker ointment on the hands and feet when the patient is up; but I have been so well satisfied with the use of the plain olive oil that I still continue it, and its simplicity and ease of application are qualities that also recommend it. Much depends on its thorough and long-continued use; and as many of our patients are seen only a few times, it is necessary before ceasing attendance to give explicit directions for the future management of the case. The treatment can be best carried out if the patient remains in bed for a prolonged period; but whether in bed or up, much care must be used when the clothing is removed. Nothing should be scattered about the floor, but all materials carefully gathered in a sheet and placed at once in the receptacle for disinfection. After getting up the hands should be well cleansed and constantly anointed, and I have known some mothers to keep the patient's hands wrapped in cotton cloths to prevent the scales from escaping.

Since adopting the measures here mentioned, my impression is that the disease is much less contagious than before. I have kept no records of cases, but those of recent date can be recalled, and I remember none in private practice within the past year when it spread to any other person after my first visit, even when isolation was impossible. Such results may be in part accidental, but I will mention some of the cases to show the extent of exposure.

CASE I.—Family containing five children between the ages of one and eleven years, none of whom was protected by previous attack. Two of these were taken sick at the same time, and at my first visit the rash was just appearing. In one the sickness was moderately severe, in the other very mild. It was impossible to keep the other children out of the sick-room, and the mother took care of them all. Three other susceptible children in the same house were occasional visitors, but none became affected.

CASE II.—Family containing five children who had never had the disease. Ages two to twelve years. One of these, aged six years, had a moderately severe attack. Rash quite abundant. Patches

on tonsils. He was kept in a separate room, but the other children were on the same floor, and the mother took care of all. No other case occurred in the family.

CASE III.—Family of three children who had never previously had the sickness. Ages six to ten years. The youngest had a severe attack with abundant rash. One of the others slept much of the time in the sick-room, and they were all taken care of by the same person. The two older ones remained well.

CASE IV.—Family containing four young persons who had never had the disease. The youngest, aged eight years, became affected. Rash well marked. Isolation was impossible. The others were frequently in the sick-room, and a woman living in the same house, mother of two small children, often visited the sick boy. No other case of the sickness occurred.

Other recent cases with a like result could be reported, but I have selected those in which there was the greatest exposure of susceptible persons.

It may be said that scarlet fever at the present time is of a mild type and not very contagious; but the group of cases first mentioned tends to show that under certain conditions the disease may be taken now as readily as ever.

DEATH-RATES AND RACE.

I will not weary you with further details of figures, which those of you who are specially interested in the subject will find in the reports of the vital statistics of the eleventh United States census, but will merely say that the corresponding data from Boston, Philadelphia, Baltimore, Washington, and from the New England States as a whole, taken with those from New York State and New York City and with those derived from a special investigation of over 10,000 Jewish families, including over 50,000 persons, lead to the following conclusions as being probable for the United States:

1. The colored race is shorter-lived than the white and has a very high infantile death-rate; it is specially liable to tuberculosis and pneumonia and less liable than the white race to malaria, yellow fever and cancer.

2. The Irish race has a rather low death-rate among its young children, but a very high one among adults, due to a considerable extent to the effects of tuberculosis, pneumonia and alcoholism.

3. The Germans appear to be particularly liable to disorders of the digestive organs and to cancer.

4. The Jews have a low death-rate and a more than average longevity; they are less affected than other races by consumption, pneumonia and alcoholism, but are especially liable to diabetes, locomotor ataxy and certain other diseases of the nervous system.—*Dr. J. S. Billings in Med. Rec.*

A NEW SYMPTOM OF CANCER.

G. Bogdan (*Brit. Med. Jour.*) relates the case of a woman, aged forty-eight, who suffered from cancer of the stomach. The disease had gone through a long period of latency. The patient presented on each cheek a patch of wine-red discoloration formed by the dilatation of the superficial venules; the stain showed out sharply against the pale yellow of the surrounding skin. On the strength of this symptom alone Bogdan was able to make a diagnosis of probable cancer at a time when there was yet no other manifest sign of that affection. He looks upon such superficial varicosities on the cheeks as a valuable help to the early recognition of certain cancers; he has seen it in about two-thirds of the cases of cancer which have come under his observation; it is particularly frequent in cases of epithelioma of the stomach and uterus, but less common in malignant disease of other organs.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

BUFFALO MEDICAL AND SURGICAL JOURNAL.

Dr. George F. Cott writes of

The Surgery of the Accessory Sinuses.

Inflammation of the sinuses is apt, he says, to be mistaken for ozena, and this is excusable when it occurs in a case of acute nasal catarrh, but when chronic it may be readily recognized.

The posterior ethmoidal and sphenoid cells open by one or more foramena into the superior meatus; the frontal sinus, the anterior ethmoidal cells and antrum of Highmore into the middle meatus; the nasal or lachrymal duct into the inferior.

In disease of the frontal sinuses headache is more or less constant, and in addition if the pus is not free to escape the roof of the orbit will be subject to pressure, causing displacement of the eyeball, amaurosis and diplopia.

If pus escapes it is bright yellow and it will be found issuing from the infundibular opening in the middle meatus by cleansing the parts with swab or spray and then applying cocaine solution.

In acute cases the ordinary treatment for the nasal affection is sufficient, but in chronic cases it is necessary to remove hypertrophied tissue from the middle turbinated bone, or even to remove some of the bone to give free exit to the pus. In some cases it is necessary to make an opening over the inner angle of the eye, to thoroughly clean the sinuses, and to pass a probe through the infundibulum into the middle meatus, followed by washing and by packing with gauze.

When the sphenoidal sinus is at fault, bright yellow pus is found dripping into the pharynx from an opening above and posterior to the middle turbinated bone. Deep-seated pain involving all the distribution of the fifth nerve is sometimes very severe. Pressure on the optic nerve may cause impaired vision or sudden total blindness.

When unrelieved the pus is apt to lead by pressure to ptosis, strabismus and exophthalmos and to affect the bony structures.

The treatment consists in removing obstructions and in opening the sinus by electric or dental engine, aided in every case by the rhinoscope. The operation is of course delicate on account of the danger of penetrating the brain.

The sinus being opened, dead bone and degenerated tissue are to be thoroughly scraped out.

In cases of ethmoidal involvement, if the secretions are retained, the following symptoms develop: Pain referred to the back of the eye and the root of the nose, impaired sense of smell, pus containing gritty particles from the broken-down bone. When the pressure of the pus is great enough the bone gives way, and a swelling may be found at the inner angle of the orbit and crepitation is found on pressure there.

The treatment consists in removal of the anterior part of the middle turbinated bone, exposing the opening into the ethmoidal cells.

The cavity is then washed or may require to be scraped and the nose packed with gauze or wool. As in sphenoidal disease, the operation requires dexterity.

In disease of the antrum of Highmore there are pain and a sense of fullness and weight below the orbit, and if the destruction last long the pain may become very severe. Difficult mastication, with a feeling as though the teeth were too long, may be noticed. At night pus may be felt running back into the pharynx, but in the upright posture is discharged from the nose.

The modern means of diagnosis is the use of the incandescent lamp. A small lamp is placed in the mouth, the lips are closed, and the room is then darkened and the current turned on. The presence of pus in quantity is shown by obstruction of the light.

The treatment is puncture through the inferior meatus or, better, through the alveolus if a tooth be missing. If carious bone be found, it will be necessary to make another opening with drill and chisel, clear the antrum and pack with gauze. Otherwise daily syringing will be sufficient.

Dr. A. L. Hall writes of the

Home Treatment of Hay Fever.

Hay fever is, he thinks, due primarily to a condition of neurasthenia, and the proper mode of treatment lies in combating this condition. The irritable respiratory apparatus responding to the pollen of plants is secondary in etiological importance.

Some cases are detailed in which treatment on these principles has enabled the patient to remain at home and yet escape without very great discomfort.

A prescription in which the author places considerable reliance is the following:

Liq. potass. arsenitis	
Ext. nucis vomicæ fluidi	ää ʒ ij
Ext. cinchonæ fluidi (detannated)	
Alcoholis	ʒ iij
Syr. aurantii	q. s. ad. ʒ xvj

M. Sig.: ʒ j or ʒ ij t.i.d., with or after meals.

The use of this preparation for at least six weeks before the annual appearance of the disorder and its continuance during the three months following is declared necessary.

Dr. A. L. Benedict writes of

Atonic Dyspepsia.

The term, he says, fell into disrepute for a time and was regarded as indicating imperfect diagnosis on the part of any one using it. Sometimes, however, after thorough study

of a case this term seems the most suitable description. Pepper recognizes the expression and applies it to a condition causing a large, flabby, tooth-marked tongue, not necessarily coated, sense of weight in the epigastrium, development of flatus, sluggish bowels, urine loaded with urates, etc.

It is improbable that there will be lack of nourishment if digestion be perfect, and the distention of the stomach is not so much due to muscular atony as it is to fermentation by micro-organisms and due to lack of hydrochloric acid.

Many healthy persons masticate imperfectly, and this fact should more than offset the want of muscular churning movements in a case where the food eaten was soft.

In atonic dyspepsia the lack of hydrochloric acid leads to insufficient digestion of proteids, therefore delayed absorption and sluggishness of the muscular movements of the stomach and the intestines.

In the irritative type the ptyalin digestion of carbohydrates is inhibited by the excess of hydrochloric acid, and the irritation caused by this excess may lead to gastric ulcer. "In high grades of acute gastritis, in the late stages of cancer and of chronic catarrh, and at the approach of death in any disease there may be a scarcity of pepsin, but under these conditions only. There is therefore no excuse for the administration of this ferment except in those cases which are better treated by the use of predigested food."

The ultimate cause of atonic dyspepsia is constitutional depression due especially to prolonged worry. It is often the first symptom of tuberculosis. Once established it leads to increased depression.

Physical examination will show the stomach relaxed, perhaps, and sagging below its normal level, but it is not dilated. Chemical examination of the contents is important, and the writer does not think a complete diagnosis possible if this be neglected. Moderate acidity will usually be found, but the hydrochloric acid is so reduced in amount that frequently it is not evident from the use of ordinary tests.

The treatment the author advocates is the administration of well-diluted hydrochloric acid. Usually from six to twelve minims of the officinal dilute acid may be given an hour after meals. If more is necessary, it may be given well diluted at short intervals at about the same period of digestion.

Since hydrochloric acid is formed from the chlorides ingested common salt should be freely used, but the author declares the use of pepsin a sign of ignorance.

To stimulate secretion and absorption strychnine may be given before meals. Hot water is also beneficial, and if a small quantity of soda be added it will serve the additional purposes of washing away any accumulated mucus and increasing the formation of acid.

Mention is made of a favorite application: the use through the stomach-tube of a spray of an oily solution of menthol, which the author has found very beneficial.

In the discussion of this paper the question arose whether lactic acid occurs normally during digestion. The author had found a substance which responded to the ordinary tests present in every case examined, and apparently most markedly present at the end of the first hour. Another speaker quoted Boas' belief that when lactic acid occurs cancer is present.

Another member present thought a properly chosen diet was of more benefit than medicine, and in choosing this cautions his patients to avoid the skin of all fruits and vegetables—grapes, apples, etc.—and regards cabbage as in the same list.

Fresh meats, fish, eggs, milk, stale bread, etc., constitute his main reliance, and he feels great confidence of successfully treating any case in which this diet is adhered to.

Dr. Wm. Redin Kirk writes of the "Constitutional Treatment of Diseases of the Female Sexual Organs" (mainly by a proprietary mixture).

Tea as a Possible Source of Plumbism.

The source of lead in most cases of plumbism is easily found. In districts where home-made wine is plentiful, the plumbism can be found due to the glaze of the earthen pots in which the wine stands for some days. In 15 cases carefully investigated, 6 were due to the wine. In 5 the tea contained lead—no other source could be found. In 2 wine was a possible source, but tea which contained lead was the more probable. In 2 no cause could be found, but the tea drunk before the illness could not be excluded.

In 1886 cases of plumbism in Odessa were traced to tea packed in lead-lined chests. The lead may be mechanically rubbed off from the chest lining. The lead lining may be acted on by the tea fermenting inside or from the chest being made of green wood. Carelessness in packing is another cause—traces of copper and chips of lead paper have been found in several small packets of tea. Infusion of tea, upon experiment, has been found to have a powerfully solvent action upon lead; in this way chips of lead paper are a danger. Of 22 different kinds of tea, 17 contained lead; 1.375 mlgms. of lead per pound was the smallest amount found and 18 mlgms. the highest. The average of all contained 5.962 mlgms. per pound. It was most unevenly distributed—of two packets of the same brand bought at the same time in the same place, one contained 1.6 mlgms. per pound and the other 18 mlgms. How far small doses are dangerous is difficult to state. One case is said to have been poisoned where only 1-357th grain of lead per gallon was found. Water containing 1 20th grain per gallon should be considered dangerous. Tea containing 6 mlgms per pound (the average of all the estimates) is equal to water containing 1-77th grain per gallon. Tea containing 18 mlgms. per pound equals water having 1-25th per gallon. Tea containing such quantities may cause plumbism in susceptible individuals, and would greatly increase the dangers from other sources, as water or home-made wine.—*Lancet.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Virchow on the Serum Treatment of Diphtheria.

The Berlin correspondent of the *British Medical Journal* writes that Virchow gave his opinion with characteristic caution. He said that he had been inclined to be skeptical as to the good results obtained in diphtheria last summer in the Kaiser and Kaiserin Friedrich Hospital, as he thought none of the cases was of the severest type. In August, however, the supply of antitoxin fell short, and since then the mortality from diphtheria in the hospital had risen remarkably, showing that the epidemic was severe in character. He summed up his opinion as follows: The serum exercises a strong protective influence for weeks, perhaps months, say three or four months. Whether this influence be lasting can be shown only by further experience. Moreover, this alone can furnish the answer to the cardinal question, Is it a specific for diphtheria? But much has already been gained when, for instance, it is possible in a family where three or four children are down with diphtheria to immunize even one child, and this, in all probability, can be done by the serum.

Antiseptic Mouth Wash.

E. Maurel (*La Med. Mod., Gaillard's*) presents the following formula:

Alcohol	ʒ ij
Tincture of eucalyptus	ʒ v
Tincture of cinnamon	ʒ ijss
Tincture of rosemary	ʒ j¼

M. Sig.: A teaspoonful to a glass of warm water.

Treatment of Seborrhœic Eczema in Children.

Feulard (*Jour. des Prat.*) observes that attention must be given in the first place to the diet, which should be limited to milk, with the addition, in older children, of eggs. In the local treatment the first step is the removal of crusts, which may be effected by using warm coal-tar lotions, preceded, if necessary, by poultices. After the crusts have been removed he uses gauze compresses soaked in a solution of resorcin (6 in 1,000). These are kept constantly applied to the scalp by day and are applied frequently to the face. By night an ointment is used, consisting of one part of balsam of Peru to thirty parts of vaseline. Later he uses fine starch powder or a powder consisting of equal parts of starch and carbonate of bismuth. Recovery is rapid if the instructions as to diet are strictly observed and the dressings used with regularity.

Hints on Treatment of Diabetes.

Dr. Solomon Solis Cohen, writing on the different forms of diabetes mellitus, gives this suggestive advice with respect to treatment: Examine the urine frequently, and administer alkalies freely if this excretion be too acid or if the sugar have diminished suddenly. As constipation is a precursor of diabetes coma, it must be prevented by giving phosphate of sodium in doses according to the effect produced. This may be combined with 1-64 grain of arseniate of sodium, a useful expedient. Strontium bromide in doses of twenty grains may be given in cases of diabetes in the gouty and obese. It is a stomach tonic, promotes digestion, relieves flatulence, increases general nutrition, and keeps the blood moderately alkaline. Strontium lactate can be alternated with the strontium bromide. From time to time arseniate of strychnine, 1-128 grain six times daily, is given as a general nervous tonic and stimulant. Dr. Cohen believes in codeine; and, following Sir Benjamin W. Richardson, he gives it in solution with hydrogen dioxide. Thus:

Codeinæ phosphatus	grs. ij
Spiritus rectificati	drams iv
Acidi phosphorici diluti	drams ij
Glycerini	drams vj

Solutionis hydrogen dioxidi (10 vol.) ad ounce of misce.

Two teaspoonfuls to be taken in three ounces of water.

With this is enjoined an alkaline course, arsenic being sometimes added. Hydrogen dioxide, ozonic ether and oxygen have been advocated on the presumption that they bring about increased oxidation of the sugar or ·condary products circulation in the bloo Dietetic treatment of course precedes medic ion. Don't try to cut off bread and potatoe together. Gluten bread is not reliable and not palatable. Try to make up by fats for the exclusion of the starches. Keep your patients warm and protected; cold is their greatest enemy. Examine the urine for organic acids and keep the blood alkaline. In the matter of diet be strict enough to diminish polyuria and glycosuria, and if possible secure their disappearance, provided you can at the same time keep the patient comfortable, but under any circumstances make the patient comfortable.—*Ther. Gaz.*

Morning Diarrhœa and Its Treatment.

Dr. P. L. Brunton (*Med. Week*) considers the special form of diarrhœa which occurs in the morning as due to a chronic state of irritation or congestion of the sigmoid flexure or of the rectum. If this congestion is too frequently repeated, it is gradually changed into an inflammatory condition which may ultimately result in the production of intestinal ulceration. In this form of diarrhœa

the region of the sigmoid flexure is very tender. On palpation the intestine is frequently found to be contracted to a thick, hard band.

As the capital point in the treatment of this affection is mentioned absolute abstinence from the ingestion of liquids of any description for a period of from twelve to fifteen hours preceding the moment at which the diarrhœa usually appears, that is to say after five or six o'clock in the evening. The most that should be permitted, if the patient suffers greatly from thirst, is a few mouthfuls of liquid. During the day beverages may be allowed, but only in moderate quantities. In addition, the irritability of the intestine is to be allayed by the administration of bismuth subnitrate and sodium bicarbonate. In obstinate cases, it is stated, massage may be advantageously employed.

Intrarectal Application of Ice.

Drs. Pasterunatzky and Koulbine (*Sem. Med.*) are reported to have successfully resorted to the intrarectal introduction of ice in the treatment of excessive hemorrhoidal bleeding, in rectitis, weakening of the anal sphincter from persistent diarrhœa (sometimes followed by rectal prolapse), ulceration and cancer of the rectum, and, finally, collapse due to poisoning by opium, morphine, chloroform, alcohol and analogous substances.

The pieces of ice should have a conical shape and a length of 20–30 cm. (8–12 in.). They melt in the intestine within four to five minutes. From two to ten, and even more, may be introduced daily.

These intrarectal applications of ice for a moment produce a rather disagreeable sensation, accompanied with contraction of the sphincter; but, on the whole, they are usually well tolerated, it is stated. They exert upon the intestine a hæmostatic, antiphlogistic and sedative influence, and constitute a very prompt palliative remedy against false labor pains, pain in the rectum and other annoying sensations often felt in that region (such as burning, prickling, intense pruritus, throbbing, heaviness, etc.). With febrile patients they bring about an abatement of the fever and ameliorate their subjective condition. By reflex action, finally, they stimulate the heart and respiration, and also increase blood-pressure, which explains their beneficent action in collapse.

The Cure of Inebriety.

The drunkard is curable in at least one-third of the cases. The basis of cure is forced and prolonged total abstinence, which should be instituted at once Delirium tremens does not result from suddenly stopping the alcohol; its only results are headache, malaise and sweating. The treatment should be undertaken only where the patient may have calm surroundings and a military discipline; some drink, which will quench the patient's thirst and give him pleasure, should be substituted for the alcohol. Treatment should last at least for one year, and before it is terminated the force of the patient's resistance should be tried. When the treatment is concluded some moderate surveillance should still be exercised. If a certain trade or profession has been a causative factor it should be abandoned.—*Marandon de Monytel in Annal. Med. Psych.*

Dental Manifestations of Gout.

Kirk (*Lancet*): The coexistence of certain forms of suppurative gingivitis and gouty diathesis has long been known. Dr. Peirce, of Philadelphia, has shown that the calcareous deposits taken from the roots of teeth lost from pyorrhœa alveolaris contain, besides the usual calcium carbonate, considerable uric acid and urates of calcium and sodium. He concludes that the deposits upon the roots of such teeth are not salivary, but hemic in origin, and that pyorrhœa alveolaris is simply a local manifestation of gout. As further evidence of the correctness of these conclusions, the author has found that after thorough local treatment the gingivitis will disappear and have no tendency to return. He has found a marked acidity of the secretions of the mucous glands of the mouth in such cases, which brings about local decalcification of the enamel. He first used cream of tartar to correct this acidity. He afterward had a lithium tartrate prepared, which gave much more satisfactory results than any other alkali used. The promptness with which it acts is sometimes astonishing. After three doses of five grains each all symptoms sometimes subside.

Morphinomania in the Medical Profession.

Dr. Jules Rochard, in the *Union Medicale*, draws a gloomy picture of the increase of the morphine habit in France and elsewhere. The habit, he finds, becomes incurable at the end of six months of indulgence. The fair sex and the doctors are, in his opinion, the most deeply addicted to morphine. He draws an unpleasant comparison between the behavior of each kind of delinquent. Women, he says, delight in declaring how they indulge in this vice, and show ornamental hypodermic syringes to their friends. Dr. Notet states that a lady having broken the needle of her syringe in a remote country village, wounded her skin with scissors and thrust the stump of the needle into the wound, injecting herself in this manner till a new syringe arrived from Paris. Men, Dr. Rochard declares, and especially medical men, the bulk of male morphine injectors, take the greatest pains to hide their vice. Hence the precise number cannot be estimated. He believes, however, that doctors and persons associated with them form nearly half the total of men addicted to morphine.—*Med. Rec.*

Breakfast for Chlorotic Girls.

Dr. Carl Von Noorden, in the *International Medical Magazine*, speaking of the dietetic treatment of chlorosis, says: "Most chlorotic

girls feel weakest and worn out during the hours of the forenoon and incapable of any proper kind of work. This condition is uncomfortable and directly harmful from the educational point of view. The best remedy is the English fashion of a good hearty meal at the beginning of the day. Chlorotic girls are advised to drink half a liter of milk of the best quality while still in bed, and to do it very slowly, taking fifteen minutes to drink the quantity prescribed. Half an hour later they should rise and be rubbed with a dry, rough woolen towel. Then comes the breakfast, consisting of a small cup of tea, one or two slices of buttered toast and plenty of meat. Two hours and a half later some bread and butter is to be eaten, together with two eggs, this to be followed by a quarter of a liter of milk. A glass of sherry is now permissible if special reasons warrant it. This morning regulation of diet makes the forenoon hours quite comfortable. Fixed rules for other meals are of less importance."

Diet in Gout.

A. Bogdanoff has studied in Professor Obolenski's clinic the influence of animal, mixed and vegetable diet in four patients, three of whom suffered from gout and the fourth from round ulcer of the stomach. The latter patient was given only milk as a food. The mixed diet was found to cause the greatest daily excretion of urine and of uric acid. The specific gravity was between that of the urine in vegetable and that in animal diet. The body-weight increased most under the influence of vegetable diet, diminished under mixed diet and fell greatly under meat diet. In the fourth patient, although the daily quantity of urine was as great, with a slightly acid reaction, the quantity of uric acid was small. The author concludes from these experiments that the diet of gouty persons should not be heavy, but nourishing, and tending to increase the number of white-blood corpuscles. For this purpose mixed diet answers best. Pure meat diet acts badly from a psychical standpoint, frequently causing a great antipathy to meat, a tendency to eat little and to drink less, and in this manner diminishing the quantity of urine considerably. Constipation is also often observed.—*Jour. Med. and Hyg.*

Tannigen, a New Intestinal Astringent.

Meyer (*Deutsche med. Woch.*) calls attention to the inefficiency of most astringents upon the lower bowel because of their destruction in the stomach or upper bowel, the large dose in which they must consequently be exhibited, and the deleterious effect of this large dose upon the stomach itself. The new compound is a pentacetate of tannin. It occurs in yellowish-gray powder, is tasteless and odorless and is slightly hygroscopic. It can be heated to 330° F. without change. It is insoluble in cold water and only slightly soluble in hot water. The action of this drug was first tried on cats. It was found that relatively large doses could be taken without interfering with the stomach in any way, and that it had a decidedly constipating effect.

Muller (*ibid.*) has tested "tannigen" on some of his patients, with the following results: The patients take the powder without any ill effects either upon the appetite or the stomach. The drug was so harmless that a definite dose was not ordered, but a knife-pointful was directed three to eight times daily. It was used in chronic diarrhœa, chronic intestinal catarrh, in some cases of recurring dysentry, and in cases of intestinal disturbance in phthisical patients. In most cases the number of stools was decreased on the day after the drug was begun. In some, as in phthisical cases, the good results lasted only so long as the drug was continued. But as soon as the drug was again commenced the diarrhœa stopped. Some of the patients took the drug for several weeks without ill effects or lessening of the good effects. The drug was also tried in a small epidemic of acute diarrhœa, and the disease in all the cases was brought quickly to an end. In the acute and subacute diarrhœas of children the drug is valueless except the diet be changed. It is also without good effect in the atrophic cases of nursing infants. He concludes that it is of most value in chronic diarrhœa and is actually curative in these cases. He thinks that it is also of great value in the diarrhœa of phthisical patients, where it can be given for a long while and will not interfere with the appetite or digestion.

SURGERY.

Cream of Tartar in the Treatment of Gonorrhœa.

Dr. Oteri (*Jour. de Med. de Paris*) has employed the cream of tartar in 280 cases of gonorrhœa, bubos, chancres and operations on the prepuce. On account of its mild action it is of service in urethral injections, even to five a day. It subdues the inflammation and arrests the discharge. It is possessed of eminent antiseptic and absorbent properties. In profuse suppuration in wounds or cavities with sinous or necrosing walls it will yield good results if applied locally. In bubos, chancres and syphilitic ulcerations, as well as in balanitis, he has found it a good local application. It is cheap, devoid of odor, painless and easily handled.

Abscess of the Hand as a Complication of Gonorrhœa.

As a recent contribution to the long list of complications of gonorrhœa which have been shown to be due to the presence of the gonococcus in the remote lesion, we have the report of a case by Horwitz (*Wein. Klin. Woch.*), in which a young man, twenty-seven years of age, who had suffered from gleet for a year, was affected by an abscess on the back of the hand. Examination of its contained pus showed the presence of the gonococcus of Neisser, both microscopically and in cultures.

In a carefully compiled introduction Horwitz reviews the cases of a similar nature which had been published up to the time of his writing.

Electric Effluvation for Chronic Leg Ulcers.

Dr. Marquant (*Med. Week*) has obtained excellent results from static electricity in the treatment of chronic leg ulcers, especially those of a varicose character. The method employed, which was originated by Professor Doumer, of Lille, is as follows: The sore is first washed with an antiseptic solution (perchloride of mercury or carbolic acid in feeble proportions) and then covered with a thin layer of absorbent cotton. The patient is placed on an insulating seat and connected with the negative pole of an electrostatic machine. The electrode is then approached to the sore, keeping it, of course, sufficiently far away so that no sparks are discharged, though near enough for the production of the electric souffle or wind. The effluvation is continued for ten minutes, after which the wound is dressed. The sittings are usually repeated three times a week.

The dressing used for the patients treated by Professor Doumer and Dr. Marquant consisted at first in sprinkling the sore with powdered subcarbonate of iron and covering it with aseptic cotton; but later on the carbonate of iron was suppressed and a simple application of absorbent cotton-wool resorted to. As this dressing is only renewed twice a week, the effluvation is practiced once in every three times through the layer of cotton, which, therefore, should be as thin as possible.

Treatment of Contusions and Lacerations of the Urethra.

Dr. Reineking formulates the treatment as follows:

1. Make careful attempts to introduce a soft catheter, and if successful leave it in place for five or six days, irrigating the bladder daily with boric-acid solution. After that time the reintroduction, if necessary, will generally be easy.
2. Avoid metallic or other stiff instruments; this will also do away with the necessity of general anæsthesia for purposes of catheterization.
3. When a soft catheter cannot be introduced, an external urethrotomy should be performed. It should be done at the earliest possible time, so as to avoid extravasation of urine and infection of the peri-urethral tissues.
4. If for any reason a urethrotomy cannot be done, we have in supra-pubic puncture a safe, efficient and easily executed procedure for purposes of temporary or even permanent relief.
5. As a substitute for puncture, supra-pubic cystotomy may be resorted to.—*Milwaukee Med. Jour.*

Gunshot Wounds of the Intestine.

In an article on this subject Dr. Hefeelfinger in the Texas *Courier-Record* draws the following conclusions:

1. Laparotomy is the only rational procedure in all cases of gunshot wounds of the abdomen where there is reasonable evidence that the ball has entered the abdominal cavity, and each moment's delay will materially lessen the chances of recovery.
2. If there is a reasonable doubt as to whether or not the ball has entered the abdominal cavity, give the patient the benefit of that doubt by doing an early exploratory operation for diagnostic purposes.
3. In wounds of the pancreas complicating gunshot injuries of the intestine a resection of this gland may be done, care being taken not to include the head or common duct, as death invariably follows such procedure.
4. The segmented catgut rubber ring being unaffected by the imbibition of intestinal secretion is one of the very best aids in circular enterorrhaphy or lateral anastomosis.
5. A ring composed wholly of catgut is entirely worthless as an intra-intestinal support on account of its highly absorbable qualities.
6. When the Lembert stitch includes only the serous or a part of the muscular coat they do not, as a rule, ulcerate their way into the bowel, as is claimed by some, but usually become encysted and remain near their place of introduction.
7. An intestinal wound when properly treated usually becomes securely sealed in from six to twelve hours by the formation of plastic peritoneal exudation; but this must not be too confidently relied upon, as it may be very materially retarded.
8. If there arise evidences of suppurative peritonitis, do a second abdominal resection, disinfect the cavity and apply drainage.

Cancer a Local Disease.

The evidence for this doctrine has been strongly presented by Dr. Jennings, in his work on "Cancer and Its Complications," the second edition of which has been recently published in London. If cancer be a local disease, it is imperative that not only those tissues which are seen to be subjected to cancerous infiltration, but some of the surrounding tissues and the neighboring lymphatic glands should be taken away by means of the knife at as early a date as possible. The amount of personal observation given in support of this method of treatment is not very great, but the careful analysis of the work and opinions of others and the comparison of the methods of termination of the disease under different methods of treatment amply warrant Dr. Jennings in drawing very wide and general conclusions.—*Brit. Med. Jour.*

New Observations in Gonorrhœa.

At the recent meeting of the German Dermatological Association considerable time was devoted to the discussion of the etiology

of gonorrhœa, and among the interesting points brought out, an observation by Wertheim is deserving of especial attention. This careful investigator has found that gonococci obtained from the secretions of chronic gonorrhœa can be cultivated so as to acquire a high degree of virulence, and when inoculated in the urethra of the patient from whom they were derived will give rise to an intense gonorrhœal inflammation. It has been quite frequently observed that patients suffering from latent gonorrhœa at the time of marriage have infected their wives, and at a later period acquired from them in return an acute urethral inflammation. Wertheim's experiments are, therefore, of importance in affording a rational and scientific explanation of this clinical observation.—*Inter. Jour. of Surgery.*

Antiseptic Treatment of Burns.

Wilbouchewitch (dissertation, Paris) concludes an article with the above heading in the following wise:

1. Fresh superficial burns, as well as deep ones, can heal under antiseptic treatment without the production of pus.
2. If pus is produced the wound is disinfected, and the course remains the same as if non-infected. But if the pus is of long standing and the wound begins to granulate, then disinfection is not possible.
3. To disinfect widespread burns an anæsthetic will often be necessary, and to this end chloroform is best suited.
4. If the wound is non-purulent the unnecessary use of an antiseptic hinders the healing process.
5. Antisepsis is the best analgesic.
6. Burns heal rapidly under the antiseptic treatment. Burns of the second degree require eight days; of the third degree, from two to three weeks.
7. Burns of the second and third degree heal without trace remaining; of the fourth degree, cause a scar, which does not retract, while this will be smoother the less the amount of pus.

Pott's Disease in Children.

Pott's disease in children is so often recognized so late in its course that all hope for improvement is futile. The early symptoms and signs which should always be looked for are laid down by Dr. Dillon Brown in the *Archives of Pediatrics* in the following list of different points:

1. The pain, general disability and sickness are out of proportion to the apparent amount of spinal disease.
2. The onset is alarming and the progress of the disease more rapid than in tubercular caries—the paralysis being an early symptom and the deformity appearing even in a few weeks after the beginning of the symptoms.
3. The local pain is intense; and the peripheral pains, the deformity, the extreme spinal disability and paralysis, including incontinence of urine and feces, rapidly grow worse in spite of rest in bed and instrumental support.
4. Secondary disease soon appears, rapid emaciation and marked cachexia are seen, and the patient does not live more than six or eight months.

Whether a vertebral caries is due to syphilis or to tuberculosis is of immense importance as regards prognosis and treatment. In both diseases the symptoms are almost identical, and the diagnosis must be based upon the history, the presence or absence of other evidences of syphilis and the result of treatment. In tuberculosis there is more likely to be an evening rise in temperature, and the pus and debris may contain tubercle bacilli. Syphilis is suggested by nocturnal pains and the involvement with chronic disease of some other joint or joints or some other part of the spine.

Double Suppurative Orchitis, Causing Peritonitis and Death.

Hornus (*Centralblatt fur Chirurgie*) reports a very unusual case in which a soldier without having received an injury, without gonorrhœa, mumps or any other preceding disease, was suddenly attacked by an acute double suppurative epididymitis and orchitis which spread up the spermatic cord to the peritoneal cavity. Suppurative peritonitis followed with death in five days from the onset of the trouble. At the autopsy the testicular substance was found to be replaced by pus. It should be mentioned that at the time there were some cases of mumps in the same barracks.

GYNECOLOGY.

The Treatment of Inflammatory Diseases of the Pelvis.

In a paper on this important subject Dr. J. Henry Carstens, in the *American Journal of Obstetrics*, speaks strongly in favor of conservative treatment and urges the necessity of proper treatment by the general practitioner, who is usually the first to see them. He closes in the following words:

1. Let the general practitioner most conscientiously and carefully treat gonorrhœal infection in women.
2. Let the family physician and obstetrician most carefully manage confinements aseptically, and in the treatment of miscarriages be most thorough and not trust the vis medicatrix naturæ, but carefully clean out the uterine cavity.
3. Girls or young women who have leucorrhea and pelvic pain, the result of accident or not, should be most carefully and early treated before mischief has been done.
4. In cases of acute inflammation judge each by itself. If the symptoms are mild, palliative treatment with absolute rest will be proper and an operation can be performed later.
5. Cases of six or eight weeks' standing with sepsis should be operated on promptly.

6. When operating try and remove all diseased tissues if you expect your patient to get well promptly and perfectly. If you cannot and a second operation is necessary, tell your patient or the friends immediately, otherwise you will bring abdominal surgery into bad repute.

Hysterorrhaphy for Retroversion.

The operation of stitching the uterus to the anterior abdominal wall for retroversion of long standing has given excellent results. In a paper in the *American Journal of Obstetrics* on "Mechanical and Surgical Methods of Treating Retro-Displacements of the Uterus," by Alfred C. Carpenter, of New York, the method of hysterorrhaphy is spoken of as one of the foremost at our command. Its technique is simple. With the usual antiseptic precautions an incision is made in the median line of the abdomen midway between the umbilicus and pubes; two fingers are introduced; adhesions, if they exist, are broken up and the fundus uteri brought up into the abdominal wound and grasped with vulsellum forceps. With a knife or small pair of curved scissors the peritoneum is denuded from the anterior surface for about the size of a twenty-five cent piece. Then two or three sutures of heavy silkworm gut are introduced through the uterine tissue, taking a generous hold so there will be no danger of their cutting out by the traction put upon them by the weight of the organ, and at the same time guarding against penetrating the uterine cavity. These sutures are then carried through the entire abdominal wall on either side of the incision and are tied, thus fastening the fundus in the median line midway between the umbilicus and pubes. The sutures are allowed to remain about three weeks to assure firm union between fundus and abdominal wall.

The Glycerine Suppository as a Substitute for the Glycerine Tampon.

Dr. J. T. Graham, in a paper read before the Virginia Medical Society, speaks of the general use of the glycerine tampon. The only way in which glycerine relieves congestion of the uterus and its adnexa is by depleting the engorged vessels of these organs by means of the process of osmosis on account of the great affinity glycerine has for water. Reasoning from this fact, he concluded that glycerine in the solid state would have a greater effect upon the inflamed parts to which it might be applied because it would take up a greater amount of serum and the effect would be more prolonged on account of the gradual dissolving of the glycerine. He therefore introduced into the vagina, close up to the cervix, an ordinary rectal glycerine suppository and held it in place by a pledget of wool. The effect was much superior to that of the glycerine applied with the tampon. He also had glycerine suppositories made containing one or two grains each of alum and thymol. The advantages of the glycerine suppository may be stated as follows:

1. Easy application, as it does not require the use of the speculum.
2. Its greater and more prolonged effect, its action extending at least over a period of thirty-six hours.
3. It can be used in the treatment of the virgin without the use of the speculum and will remain in place without the pledget of wool; or if it seem best the patient can be taught to apply it herself.—*Med. Review.*

PATHOLOGY.

Extreme Cardiac Dislocation

A fully described and clearly illustrated case of extreme left cardiac displacement occurring in a woman of forty-six years is recorded by Heyse (*Centralblt. f. klin. Med.*). The apex-beat was distinctly visible under the angle of the scapula, and the precordial dullness could be made out to the left side posteriorly, immediately over the hepatic and splenic areas of dullness, while at its usual position in the left front there was pulmonary resonance. The etiology of this extreme cardiac displacement is of special interest, which the author, after the exclusion of other forces, especially of old-standing pleuritic adhesion, refers to arrested development of the left lower pulmonary lobe. Analogous observations in literature, on which the author bases his opinions, make this very probable, and we must refer for an estimation of this relationship to the ample statements in the work itself.

OBSTETRICS.

A Sign of Breech Presentation.

In *La Clinique Internal* Pinard asserts that when, in a woman who has passed the sixth month of pregnancy, a sharp pain is produced by placing the hand on the fundus uteri, it may be almost affirmed that there is a breech presentation. The fact is very frequent, although not constant, being present in about 70 per cent. of cases. The pain is sometimes spontaneous, and if version is performed it disappears. Pinard claims that the pain is due to the "irregular distention produced by the rounded mass of the head," but he does not explain how an irregular distention can be produced by a rounded mass.

Vaginal Secretions in Parturient Women.

Last month some statistics were given on antiseptic obstetrics. Since then we read that Doderlein, Winter, Steffek and others claim to have found pathogenic micrococci, particularly the staphylococcus albus and aureus and other pus-producing microbes, in the vaginal secretions of women after labor. On the other hand, Konig examined the vaginal secretions of 100 women after labor who were aseptic at the period of labor, and found in the lochia more frequently the streptococcus, seldom the staphylococcus

aureus and never the staphylococcus albus. In 300 pregnant women he found the vaginal secretions to be acid, and concluded that in pathological conditions the secretions attain a much higher degree of acidity, so that the streptococcus pyogenes could hardly thrive therein, and he was unable to secure cultures of this germ. With the exception of the thrush and gonococcus germ, he concludes that the vagina of every untouched pregnant woman contains nothing pathogenic and is therefore aseptic. He considers vaginal injections of antiseptics dangerous to the ordinary patient, in that they may chemically lessen the resistance of the tissues to bacteria and may increase the intensity of septic endometritis by washing bacteria into the uterine cavity.

This is another instance of disagreement among so-called authorities, and leaves nothing for the humble practitioner to do but read both sides and then use his own good judgment. Every experienced physician knows that unless he carries poison into the vaginal canal on an unclean finger, in private practice, the kind most of us do, there is little reason to fear these pathogenic microbes. Cleanliness alone is all that is usually required either before or after labor; but at the same time it is quite certain that there are advantages and disadvantages in each method. A hot sublimate or carbolic injection during labor shrivels and contracts the vaginal mucous membrane by contracting the capillaries, removes from it its natural lubricating secretion, thus largely augmenting the friction between the head and the vaginal walls, retarding the progress of labor and necessitating greater powers of expulsion. After labor, when it is desirable to use a wash for cleansing purposes only, simple, plain borax dissolved in warm boiled water will be found pleasant and efficient. Let the solution be of about the specific gravity of the blood so as not to encourage osmosis.

Strychnine as a Prophylactic in Weak Labor Pains.

Dr. Duff (*Centralblatt f. Gynakologie*) employs strychnine as a prophylactic in decreased muscular tonus and general weakness of pregnant women, as well as in cases giving a history of weak and irregular uterine contractions in previous labors, distinct weakness and flaccidity of the abdominal muscles and post-partum hemorrhages from faulty contraction of the uterus. He prescribes 1-64 gr. of the drug three times a day, commencing six or eight weeks before the date of the expected labor; eight days before the event the dose may be increased to 1-48 and 1-32 gr. The results are claimed to be very satisfactory.

Unconscious Delivery.

Le Blond (*Jour. de med. de Paris*) related in July a remarkable case before the Medico-Legal Society of Paris. A woman, aged twenty-seven, who had been seduced and deserted, was seized with slight colicky pains, but continued to work. In the course of the following night she was attacked with still more severe pain. Thinking that an action of the bowels would give relief, she sat upon her chamber utensil; on straining, a live child was born. This alarmed her greatly, but she cut the cord with scissors, wrapped the infant in a cloth and walked downstairs, telling the people in the house, in fear and trembling, what had happened. Violent flooding set in. The cord had not been tied. Early in the morning Le Blond saw the patient and found the placenta still in the vagina. He extracted it. The mother and child did very well. Had the child died the mother would have been very strongly suspected of murder, especially if she had attempted to defecate in a public privy, in which case the child would almost inevitably have been killed.

NEWS AND MISCELLANY.

Sanitary Climatology.

U. S. Department of Agriculture,
Weather Bureau,
Washington, D. C., January 2, 1895.

The interest manifested by every class of people in the subject of climate and its influence on health and disease has determined the Honorable the Secretary of Agriculture, through the medium of the Weather Bureau, to undertake the systematic investigation of the subject.

It is hoped to make the proposed investigation of interest and value to all, but especially to the medical and sanitary professions and to the large number of persons who seek, by visitation of health resorts and change of climate, either to restore health or prolong lives incurably affected or to ward off threatened disease.

The study of the climates of the country in connection with the indigenous diseases should be of material service to every community in showing to what degree local climatic peculiarities may favor or combat the development of the different diseases, and by suggesting, in many instances, supplementary sanitary precautions; also by indicating to what parts of the country invalids and health seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases.

The hearty co-operation of the various boards of health, public sanitary authorities, sanitary associations and societies and of physicians who may feel an interest in the work is asked to achieve and perfect the aims of this investigation.

No compensation can be offered for this co-operation other than to send, free of cost, the publications of the bureau bearing upon climatology and its relation to health and disease to all those who assist in the work.

Co-operation will consist in sending to this office reports of vital statistics from the various localities. That these reports may be of value, it is evident to all that they should be

accurate and complete and be rendered promptly and regularly. Blank forms of reports have been prepared so as to occasion as little trouble and labor as possible on the part of the reporter, and will be furnished by the bureau on application.

At the very beginning of the investigation it is not possible to outline precisely the channels through which the results obtained will be made public, but it is hoped to publish a periodical devoted to climatology and its relations to health and disease. The publication will probably resemble in size and general appearance the present *Monthly Weather Review*, the subject-matter being, of course, different.

More detailed information will be furnished on application.

MARK W. HARRINGTON,
Chief of Bureau.

MEETINGS OF STATE MEDICAL SOCIETIES FOR 1895.

Society.	Name and Address of Secretary.	Time and Place of Meeting.

ORIGINAL ARTICLES.

AN ETHICAL VIEW OF A MEDICAL QUESTION.

MADANA F. DEHART, M.D., JERSEY CITY, N. J.

Herbert Spencer in his "Synthetic Philosophy" says: "In the history of humanity as written, the saddest part concerns the treatment of women; and had we before us the unwritten history, we should find the part still sadder. I say the saddest part, because though there have been many things more conspicuously dreadful—cannibalism, the torturing of prisoners, the sacrificing of victims to ghosts and gods—these have been occasional; whereas the brutal treatment of women has been universal and constant. In looking first at their state of subjection among the semi-civilized, we pass to the uncivilized and observe the lives of hardship borne by nearly all of them—if we think what must have gone on among those still ruder peoples who, for so many thousand years, roamed over the uncultivated earth, we shall infer that the amount of suffering which has been and still is borne by women is utterly beyond imagination. As I have before pointed out, this ill-treatment of women has been an unavoidable concomitant of the chronic struggle for life among tribes, which is still going on in some places, and once was universal.

"The brutality fostered in men by their dealings with enemies unconsciously operated throughout their daily lives. The weakest went to the wall inside the tribe as well as outside the tribe. The utter absence of sympathy made it inevitable that women should suffer from the egoism of men, without any limit save their ability to bear the entailed hardships. Passing this limit, the ill-treatment by rendering the women incapable of rearing a due number of children, brought about disappearance of the tribe; and we may safely assume that multitudes of tribes disappeared from this cause.

"Only during these later periods of human history in which the destructive passions have not been so constantly excited by the struggle for existence between societies small and large, has the treatment of women slowly become less brutal; and only during the same period has there been growing up among men, a perception that women have certain claims upon them, and a sentiment responsive to this perception."

Mr. Spencer ascribes this change in the conduct of men to women to the fact that character has changed and that customs have been gradually ameliorated, rather than to the fact that they recognize and respect the true ethical basis for this better treatment, and he says that as long as the code of conduct which regulates the general relation of the sexes is thought of as conventional in its origin, it is more apt to be disregarded than when it is seen to

originate in that form of beneficence which seeks to make less unequal the lives of those to whom nature has given unequal advantages.

The pages of fiction tell in glowing words the same story, and Effie Deans, Hetty Sornl, Tess of the d'Ubervilles, Trilby and many other heroines, while they excite our sympathy for their sufferings, rouse in us indignation that penalty should be so unequally distributed and that artificial social distinctions should discriminate so unjustly against those on whom nature has laid the heaviest burdens. Even the medical journals, which are supposed to deal with the purely scientific aspects of life, contain many records and record many pathetic tragedies second to none in fiction to those who are gifted with sufficient imagination to fill out these statistics with the sentiments and feelings which must always go along with them in real life, making us realize that there is yet much to be done and suffered before the true ethical relation between the sexes is reached.

The subject is so difficult, it is so intrenched with prejudices and so many vested interests seem to be enlisted to perpetuate the present injustice, that but for its great importance to the race as well as to individual happiness, we would gladly let it alone, to be cured by the slow process by which other relics of barbarism have gradually disappeared.

It is impossible to tell just how much influence the protests of outraged womanhood against her wrongs may have had in bringing about these changes. It has been said that those who would be free themselves must strike the blow, and the great dramatist tells us that the fault is not in our stars, but in ourselves, that we are underlings. If this is true, silent endurance of wrong sometime ceases to be a virtue, and at last the time comes when it is a manifest duty to tell the truth as we see it, that the cause of justice may have the benefit to be gained from different points of view.

In a recent article in THE REPORTER, entitled "The Marriage of Syphilitics," a physician discusses the right of such persons to marry, and he assumes that all about whom there could be any such question, are men. After discoursing on the great danger to which he exposes his innocent wife and unborn children, if his physician should make a mistake and pronounce him cured when he was not, he says that after he had been thoroughly treated and apparently cured, he should have no hesitation in advising him to marry, as it would be a great hardship to prevent his having the advantages of matrimony. The physical barrier of positive contagious disease being removed, there seems to be no thought given to the lowered vitality and general physical deterioration which he would bring to the marriage union—none to the mental and moral defects with which such diseases are frequently associated, and which often render a happy marriage impossible. There is no suggestion that he should choose a woman similarly afflicted, to whom there would be comparatively little risk. and with whom, should the children all die or be hopelessly idiotic or diseased, there could be no occasion for recriminations, but together they could bemoan their loss and repent of their folly. There is no suggestion that he should plainly state the case to the fair, innocent girl he proposes to invite to share with him the unpleasant harvest which he must reap from the crop of wild oats sown so liberally. Simple justice would seem to dictate such a course, to say nothing of the beneficence which we are told should characterize the relations between husband and wife.

In the same number of the journal, two cases are cited where men contracted gonorrhœa and gave it to their wives, they soon showing the usual symptoms, urethritis, vaginitis with pelvic inflammation, and the usual unconsciousness of the cause of their trouble, with the usual pathetic confidence in the integrity of their husbands, and the narrator asserts that these cases gave him so much "food for reflection" that he brought them to the knowledge of the medical society. There is no record of an operation to remove the poor offending organs which had come to such grief in their legitimate work of perpetuating the race. It will no doubt come later, when these women will make this last offering to the cause, and let us hope it will be placed to their credit in this long and unequal account. In the discussion which followed there was much questioning about just how long, if ever, it was safe for a man to marry after having been apparently cured of this dis-

ease; one gentleman declaring that no man wished to give his wife gonorrhœa, whether she was newly married or otherwise, and especially since so many pelvic diseases which required extensive operative procedure to relieve are due to this cause. He said that the question ought to be discussed and settled, as many authorities maintain that no woman ever marries a man who has had gonorrhœa but suffers in some way from its effects.

These facts turn a powerful light on the causes of disease among women, showing that much which has been usually attributed to her folly, has a different cause. Undoubtedly tight lacing, heavy skirts, imprudence during menstruation and after childbirth, with unwise efforts to prevent conception, may make her less able to contend successfully with these poisonous germs introduced from without, and less able to recover after the frequent operations which are necessary to remove her ovaries and tubes, but they can hardly be looked on as the real cause of her life-long invalidism. It did not appear, from anything said, what would be considered proper advice to a woman under similar circumstances, but one can safely conjecture that if there were no misgivings about giving her a clean bill of health, there would be great fears entertained lest she might not be morally fit to train children to lives of usefulness and honor, or a suitable companion for a virtuous and honorable man, as there might be some intangible and subtle changes due to her past life which neither drugs nor the most genuine repentance could efface.

The reason for this difference in treatment is hard to justify on any ethical grounds, and though in many ways women are better off to-day than in earlier times, there is yet a long distance to go before we reach that highest form of the sexual relation of which evolutionists prophesy, when each is anxious to make a sacrifice rather than accept one.

ALBUMINURIA AND NEPHRITIS IN CHILDREN.*

Dr. P. Le GENDRE, Paris, France.

I have designedly separated these two terms, albuminuria and nephritis, as they are not necessarily associated; for albuminuria is present in a good number of morbid conditions without being connected with a renal lesion, and during the course of a nephritis it may disappear or be present in but traces. I shall consider, successively, albuminuria in the new-born, in childhood and in youth.

Examination of the urine should be made in children of every age as well as in adults, though it undoubtedly presents difficulties in nurslings on account of the difficulty of obtaining pure urine. One may, however, succeed in this by tying a sack of goldbeater's skin to the child's penis. Albumin has been found in the urine of the new-born. In tedious labors this has been attributed to asphyxia of the child. In those cases where it is noticed after an easy labor, it has been attributed to the sudden alterations in the circulation which take place at the moment of birth. Thus there follows a period of unbalancing of the vascular equilibrium which gives rise to engorgement of the capillaries of certain regions, and notably to an increase of pressure in the renal arteries. The consequence of this may be in certain cases an immigration of blood-corpuscles into the uriniferous tubules and consequent albuminuria, which favors a sort of transitory desquamation of the renal epithelium, especially that of the glomeruli, which is still but little resistant. Therefore one will find in the urinary sediment hyaline casts, epithelial *debris* and urates. The albuminuria of the new-born does not last longer than a week; it presents no active therapeutic indications. One will protect the child from cold by wrapping it in cotton or by placing it into a *couveuse*. Nursing should be conducted with prudence,

*A clinical lecture delivered at Hopital Trousseau, Paris, France. Translated by F. H. Pritchard, M.D., from La Semaine Medicale, No. 70, 1894.

the skin might be rubbed, and in case the urine is scanty one might give daily a rectal injection of boiled water.

If albuminuria is regarded as exceptional during the first years of life, it is because the majority of physicians do not look for it except when convulsions and edema invite urinalysis. But if one examine the urine of children who are seemingly well, but living in large numbers together, as in orphan asylums, a proportion of from 6 to 40 out of 100 will present albuminuria. Now, all of these children show some disturbance of health, as impetigo, eczema, digestive troubles, stomatitis, slight forms of tonsillitis or bronchitis. These cases of albuminuria are, therefore, caused by the same factors which give rise to this symptom in larger children and in youths.

In this class as well as in adults, among the most frequent causes of albuminuria besides infectious diseases are gastric disturbances, especially when accompanying a dilation of the stomach with permanent stagnation of food, enteritis and certain pathological states of the liver. In dyspeptic children one may observe transitory albuminuria appearing during the period of digestion and disappearing afterward. These forms are either dependent upon imperfect function of the stomach or intestines or upon a functional insufficiency of the liver. If this latter organ permit the poisons formed in the liver to pass through it, having as it does its function to arrest and to neutralize them in part, and if the glycogenic and biliary functions are inhibited, it may cease for a time to accomplish the physiological transformation of the albuminoids derived from the food into assimilable albumin; there is produced one of those states which has been clinically baptized as "torpor of the liver," to which certain forms of albuminuria without even a transitory renal lesion may be attributed. Again, it is possible that the liver, allowing those poisons to pass which it should physiologically retain (Hegar and H. Roger), and these being eliminated by the kidney, irritate those organs and give rise to an albuminuria which is truly renal. These various forms of albuminuria of gastro-intestinal or hepatic origin are therefore dependent upon auto-intoxication. Hence with regulation of the diet intestinal antisepsis will successfully manage them.

All forms of poisoning may produce albuminuria; many drugs may do it, as carbolic acid, resorcine, mercury, etc.

In children, as in adults, there may be albuminuria of cardiac origin during the period of asystolia, from venous stagnation in the kidneys.

In growing children, as well as in weak and anemic youths, there is a form of albuminuria which has been termed cyclic. Gull, who was one of the first to study it, attributes it to a nervo-muscular atony; he considered it as almost physiological from the frequency with which it was found, and compared it with the spermatorrhœa of weak and neuropathic youths. Lecorché and Talamon think that it is connected with an alteration, though slight, of the renal parenchyma, a lesion which if cared for ends easily in recovery, but if neglected is prone to run into Bright's disease. It is easily misunderstood or overlooked, though it will not escape you if you follow the advice which I have repeated again and again, not to be satisfied with the examination of a child until you have analyzed its urine.

These cyclic albuminurias give rise to a special clinical picture. The children are languid, pale, fatigued; they easily get out of breath; they complain sometimes of palpitation of the heart; refuse to play; occasionally their appetite decreases or their digestion is disturbed and is accompanied with distention of the stomach and intestines. They suffer from persistent or periodic headaches which assume the form of a migraine, with insomnia and disturbances of vision. These patients, who are frequently regarded as anemic, are not only sufferers from albuminuria, but also often from phosphaturia, which is of importance in treatment.

Certain remedies which are too much lauded as tonics will not relieve these patients. As they are often dyspeptic, those wines which are usually prescribed to strengthen and which are especially rich in alcohol if joined with the so-called "digestive elixirs" (a pitiable abuse of our age) are to be avoided. I advise you in such cases to leave aside cinchona and iron, as well as arsenic, and turn your whole attention to the digestive tract and to the general hygiene, for the disease is usually dependent upon a vicious trans-

formation of the albuminoids in the system. Do not require that these patients eat too frequently of bloody beefsteak, for it is repugnant to them. You will especially prescribe milk diet, then eggs and milk, boiled fish, grilled meats, roast poultry, a good proportion of green vegetables, which are to be well cooked, fruits and *purees*. The nervous system may be stimulated by frictions of the skin with a hair glove or with a mixture of alcohol and turpentine. The child should be taken regularly into the open air, but with avoidance of excessive exercise. One may also employ to a certain extent either sulphurated or salt water baths. The only remedies which I have found useful are strychnine and the phosphates.

Now we must limit ourselves to a study of albuminuria of renal origin. You have seen in the hospital several examples of albuminuria associated with nephritis. In certain cases were purely acute varieties; in others you have been able to follow these into chronic forms. Again, we have been able to diagnose typical chronic varieties. The scarlatina ward especially has furnished us with numerous examples of acute and transitory nephritis. In this disease the invasion of the organism by the toxines may produce from the beginning a suppression of the functions of the kidneys. In other cases later, at the end of eight to fifteen days, secondary nephritis has been observed—a less tempestuous form which was liable to be overlooked if the child leave the hospital too soon; or if it leave off too early milk diet, it may be seized with a nephritis with anasarca, which is the type of acute nephritis of glomerular origin. It may in turn degenerate into a subacute or chronic form and become an epithelial, interstitial or mixed variety of Bright's disease.

You know that one now and then observes nephritis after measles, more frequently in small-pox and exceptionally in chicken-pox, where it has been overlooked until very recently. It is rarely seen during the course of mumps, but very frequently in typhoid fever and sometimes after the grippe.

Diphtheria is one of the diseases most frequently accompanied by nephritis. In the Blache ward there is a little girl of five years whose case I shall present you briefly. After having been sick for several days with a severe attack of diphtheria she entered, September 28th, the Bretonneau ward, where she was treated by the diphtheritic antitoxine and she was discharged apparently cured. On October 13th she reëntered the hospital with a paralysis of the velum palati, a nephritis characterized by ischuria and a great quantity of albumin in the urine, a heart-beat so weak and irregular that we were decidedly alarmed. This little patient is, however, to-day cured of her nephritis, and there only remains a slight paralysis of the palate. With the present state of our knowledge, one might ask if the diphtheria alone is to be accused of having produced a renal alteration which nearly killed our patient. Can the antitoxine act injuriously upon the kidney? "No!" answer MM. Roux and Martin. "Perhaps!" says Cartel. And I do not believe that he is wrong in making this reserve; yet prolonged observation only will settle the question. In the hospital and especially in private practice, in following the children placed under treatment by the serum, it has already been remarked that though the results are remarkable, marvelous even in the immediate effect, it may produce in some children certain side symptoms, as gastric disturbances, vomiting and cutaneous manifestations—not only urticaria, but also papular, circinated, scarlatiniform erythemas, etc.—articular pains, anuria, phosphaturia, urobilinuria and localized and transitory paralyses. One might, therefore, ask if the introduction into the blood of the serum of horses does not exercise an immediate or distant injurious influence upon the organism. I advise you to keep those children under careful surveillance which are treated thus, as well as to keep within the bounds of the necessary dosage, in order not to add by excess of zeal a sero-therapeutic intoxication to the diphtheritic.

Among those varieties of nephritis accompanying infectious diseases, there yet remain to be mentioned those which complicate certain forms of infectious tonsillitis without an exudative membrane in the throat and which are due to streptococci, staphylococci and pneumococci. Professor Bouchard and Dr. Kannenberg have made them well known. Therefore do not forget always to examine the urine of those affected with various forms of tonsillitis, for you will often derive from it important indications. Several years

ago I saw a child with frequently recurring tonsillitis which led to a considerable hypertrophy of the tonsils. After each of these attacks the child would be sick for several days and its urine would contain a notable quantity of albumin. Under the influence of a milk diet it would disappear, but reappear after another attack. Thinking that in one of the tonsils there was a focus of infection and poisoning which gave rise to these phenomena, I called in consultation the surgeon of the family, who, also of my opinion, destroyed the tonsils with the galvano-cautery. Since then the albumin has not reappeared in the patient's urine.

We might complete the list of the forms of acute nephritis by citing those which accompany or follow certain bronchopneumonias; those which are the consequence of ascending infections of the genito-urinary tract and follow a vulvitis, a cystitis, etc.; the toxic varieties, rare, however, in children, as from cantharides, and alcoholic nephritis in children who are forced to drink alcoholic beverages.

I rapidly pass in review as examples of chronic nephritis, those which result from not curing acute varieties; those accompanying paludism, renal lithiasis, a rare form in children; those dependent upon various forms of poisoning, as of intestinal origin, lead and alcohol, and that dependent upon intermittent hydronephrosis. In this latter case the renal pelvis is invaded by microbes and symptoms of pyonephrosis may supervene. Besides, we might cite tuberculous nephritis, amyloid nephritis consecutive to ancient foci of suppuration, which pour their poisons incessantly into the system. This variety is that observed in Pott's disease, in dilatations of the bronchi and in chronic bronchitis. Arterio-sclerosis is rare in children, yet in subjects who have passed through a number of infectious diseases the kidneys may undergo a sclerosis similar to that of the liver.

As to the symptomatology, it does not differ from that of adults. At the beginning of acute nephritis the urine is diminished in quantity. This is a sign which is not to be neglected. Easily noticed in children of a certain age, it is only appreciated with difficulty in nurslings. One must keep account of the number of times that the infant urinates in twenty-four hours. The density is ordinarily above the normal; its color may be rose-tinted on account of a slight admixture of blood; hence do not make your diagnosis until after examination under the microscope. We have at present in the hospital a child affected with paroxysmal hematuria, whose urine is frequently of a color varying from that of a currant to that of Malaga wine, without a single red corpuscle being discoverable. Finally, chemical analysis will permit you to recognize both the quantity and quality of the albumin.

One word on the retractility or non-retractility of the albumin, a sign which has been pointed out by Professor Bouchard as of clinical importance. If one heat the urine after having precipitated it by a coagulating reagent, one will observe that sometimes it will break up into a number of flakes which swim in the clear urine and are very distinct from it; again, it may form a single and large clot which appears more or less as a core; at other times, on the contrary, the albumin and the urine remain intimately united and the urine in spite of boiling becomes uniformly opaque. According to Professor Bouchard, retractile albumin is alone associated with lesions of the kidneys, which often are then characterized by the presence in the urine of epithelium and casts only. I have confirmed the exactness of this sign so many times that I believe it to be quite constant.

As to the symptoms of the nervous system, there are headache and disturbances of vision; the digestive system will present vomiting and obstinate diarrhœas; a dyspnœa which is very pronounced, with hardly a stethoscopic sign noticed in the respiratory tract, save here or there little areas of subcrepitant râles, which Laségue claims to be characteristic of "albuminuric bronchitis" and which are due to a pulmonary edema. As to the skin, one may observe various erythemata, prurigo with little crusts and lesions from scratching, purpura, etc. Never neglect to examine the urine when you have to do with any form of skin disease in a child. At times one may meet with articular pains which may simulate acute rheumatism. Auscultation and percussion will often enable you to perceive a gallop rhythm from hypertrophy of the heart when a chronic nephritis is under consideration. Finally, the serous membranes may be the

seat of effusions—hydrothorax, ascites, hydropericardium. But dropsy will be especially noticeable in the subcutaneous cellular tissue or as generalized anasarca, yet frequently as local edema in regions which are easily infiltrated, as the eyelids and scrotum.

The more or less rapid and natural termination of every form of acute or subacute nephritis whenever a sufficient portion of the renal parenchyma is destroyed, is uremia. Hence all treatment has as its object the prevention of this auto-intoxication of the organism which forms the chief danger of all forms of nephritis. The poisons, as Bouchard has demonstrated, are introduced into the economy by several ways: some enter along with the foods, others are derived from gastro-intestinal fermentation, while still others are formed by the cells of the organism itself. All of these poisons must be incessantly eliminated by the natural emunctories or destroyed by the liver or by interstitial oxidation. The kidney is the principal organ of elimination, and whenever it functionates incompletely auto-intoxication commences.

What treatment will enable us to prevent or to combat an already existing auto-intoxication? The first indication would be to choose a food which is as little toxic as possible. Such is milk, which contains but little potash, few organic matters, although enough to replenish the waste of the body, and which, from the lactose and various salts, possesses diuretic properties. If you cannot give milk administer water in abundance, but in small quantities frequently repeated. To favor the expulsion of poisons collected in the digestive tube, one will employ drastic purgatives, such as jalap, scammony or compound tincture of jalap. This should not be too frequently repeated, as it hinders excretion by the kidneys, which throw out more poison than either the intestinal serum or the perspiration. To increase the secretion of urine cold-water injections will be found a precious measure; they produce a spasm of the intestinal vessels which causes the blood pressure in the portal system to increase and thus favorably influences that of the kidneys. I always inquire how the child urinates, and I prescribe cold-water injections whenever I learn that it passes but little water. I have ordered so many as ten or twelve injections a day, and in cases of anuria even one every hour. In this latter condition it is convenient to inject water under the skin in the form of an artificial serum. If the little patient refuses to drink, one might introduce the water or the milk into the stomach by means of a soft catheter passed through the nostrils. I also employ cold baths, complete or partial cold packs, all of which increase the secretion of urine.

As remedies, different writers advise the salts of potash, squills, digitalis and caffeine. Do not use any of these diuretics, whose irritating action only serves to alter the renal epithelium. The various diuretic beverages owe their properties chiefly to the water and the slight quantity of the various salts of potash—the nitrates, acetates and tartrates—which they contain, but these potash salts all are to a certain degree toxic. As to digitalis, in certain cases it is a precious measure, but whenever the urine is nearly suppressed it is of itself actually dangerous. It then adds its own poisoning to that of the organism, before having succeeded in forcing the barrier, the kidneys. Caffeine does not present the same danger; it may be administered subcutaneously, as it irritates the stomach and provokes vomiting. Therefore, apart from caffeine there is but little advantage to be obtained from diuretics. The sudorifics also are of little value, for themselves eliminating but little poison, they have the disadvantage of decreasing the renal secretion. I have never seen uremic patients receive much benefit from vapor baths. Pilocarpine has been praised by different writers, but there is always the fear of an oversecretion of saliva and the bronchorrhœa which it produces, along with the diaphoresis it produces. When it was employed on Vulpian's recommendation, I have seen patients die before the crisis came on, and then with a considerable increase of the pulmonary râles. Another powerful means of combating uremia is blood-letting, but, unfortunately, this is a difficult operation in little children, as it exposes them to collapse. It has been replaced by the application of wet cups to the lumbar region, which diminish the congestion of the kidney. In Petit's triangle there is a system of emissary veins which establishes a communication between the cutaneous and renal circulation, and, as Renaut, of Lyons, has shown, it is only necessary to re-

move a slight quantity of blood from the kidney to decrease the peritubular and periglomerular edema and to reëstablish the secretion thus mechanically compromised. In older patients one may do phlebotomy, often with success; one is rarely obliged to repeat it.

As to other accessory measures, there are inhalations of oxygen and intestinal antisepsis, preferably obtained with alpha or beta naphthol or with the benzoate of bismuth-benzonaphthol. I warn you against the other intestinal antiseptics, as salol or betol, whose elimination might irritate the kidney.

To recapitulate. The various measures which I habitually employ to treat the ischuria, the anuria and uremia in acute nephritis, or in the acute exacerbations of the chronic variety are: Absolute milk diet; plenty of beverages, as water or milk diuretic drinks; intestinal antisepsis; drastic purgatives, as jalap or scammony; frequent rectal injections of cold water, either made with water which has been boiled and then allowed to cool, or with a solution of naphthol (0.20 per cent.); the cold pack; revulsives, as mustard plasters, dry cupping or leeches to the lumbar regions; injections subcutaneously of caffeine or an artificial serum; inhalations of oxygen; finally, in the grave forms blood-letting or wet cupping of the lumbar regions.

There only remains the treatment of the chronic variety after the acute attack has passed over. This is quite difficult and, it must be confessed, quite uncertain. What remedies are to be employed? Tannine has been praised, but I have never seen it give any real results. The iodides must be given with caution, yet they are of actual service in chronic nephritis with a predominance of arterio-sclerosis. I only mention the salts of strontium, about which so much noise is being made nowadays, I have seen them diminish the albumin for a short time, after which it would reappear in greater quantities than ever. The phosphates act as tonics, but not upon the kidneys. Therefore, but few or no medicines.

The hygiene should be carefully attended to. You will recommed the parents to keep their child with nephritis from taking cold by covering its skin with flannel; the skin must be kept functionating well by dry-rubbing it with a mixture of alcohol and turpentine. To avoid damp cold, you will advise sending the child, if it is possible, to the south during the wet and damp months; at all events have it occupy a dry room which looks toward the south. You will also continue the milk diet, which must be interrupted from time to time, as patients grow tired of it, and it is not sufficient to support the body. You will therefore make out a dietary with care to eliminate the harmful foods: meat, and above all that which is but little boiled, as well as those foods which are extracted from it, soup, blood or bouillon; fish, which sometimes contains very poisonous toxines; game, which is still more injurious, as it is often too high. As to vegetables, you will leave out asparagus, gooseberries, tomatoes and cresses. What foods are therefore allowable in chronic nephritis besides milk? Farinaceous and starchy foods; eggs, which are not harmful if well boiled, as their albumen is not the same as that of the blood and they do not increase the albuminuria; green vegetables and certain fruits. As a beverage, always milk, either pure or diluted with a weak mineral water. Alcohol in all forms is forbidden; no wine, no beer. If amelioration set in one may, at a certain time, return to the use of meat, commencing with white meat which is well cooked.

Therefore you have a certain alimentary gamut which you must run through, and which, with prudence, you will interrupt from time to time; putting your patient upon an absolute milk diet and then mitigating it somewhat. In this manner you will greatly lengthen your patient's life by preventing an extension of the renal lesion, for it has been demonstrated that a very small portion of renal parenchyma suffices to sustain existence, with the condition that no acute exacerbation set in from congestion nor a lesion due to a secondary infection, as from a broncho-pneumonia, erysipelas, etc., be added.

During the course of this lecture you have noticed that I rejected the use of drugs, especially when their use was of doubtful value, but the subject is peculiarly appropriate to demonstrate to you that one may carry out excellent and efficacious therapeutic measures without having recourse to drugs. This is more especially and strikingly true in children's diseases than in other branches of medicine, and I shall esteem myself happy if I have succeeded in impressing upon you this which I hold as profound conviction.

COMMUNICATIONS.

THE INDICATIONS AND NATURE OF TREATMENT IN SEVERE ABDOMINAL INJURIES AND INTRA-ABDOMINAL HEMORRHAGES UNACCOMPANIED BY EXTERNAL EVIDENCE OF VIOLENCE.*

JOHN B. DEAVER, M.D. PHILADELPHIA.†

Every surgeon has undoubtedly at some time in his experience, either in private or hospital practice, met with cases coming under the class covered by the title of this paper. These are cases in which the history and general condition of the patient give the impression that there is a serious lesion within the abdomen, and yet, upon examination, we find total absence or only slight evidences of injury. The tendency, I fear with many, is to treat these patients tentatively, only to be awakened at the autopsy to the fact that a rupture or a tear existed in the abdominal cavity, which, by early radical operation, could have been relieved.

The mortality in these cases is appalling; references to the literature of the subject will amply bear out this statement, which is readily accounted for by the nature of the injuries. Where the lesion is of the liver or spleen, if the patient does not die of shock or hemorrhage, a violent peritonitis supervenes to which he shortly succumbs. If the liver, spleen or kidneys are involved, death from hemorrhage may ensue in a very short time. Should the stomach, intestine or bladder be ruptured and their contents poured into the peritoneal cavity, death from peritonitis is the result. In rupture of the mesentery the danger is from hemorrhage, yet when the opening in the mesentery is small a clot may form sufficiently large to control the bleeding. Should death occur under these circumstances it would be the result of peritonitis caused by the free blood in the peritoneal cavity. I report a case of this character where recovery followed immediate operation. In ruptured extra-uterine pregnancy death is due either to hemorrhage or peritonitis.

The usual history of these cases, with the exception of extra-uterine pregnancy, is that the patient has received a direct injury to the abdomen, which is found to be unaccompanied by external evidence. These injuries may result from railroad accidents, from being caught between shifting cars, or from blows upon the abdomen received in various ways.

This class of injuries is quite common in military surgery, more so in the past when spherical balls were used and only a low velocity attained. A majority were supposed to be caused by the violence of the wind displaced by the passing ball, but we now know that they were due to the impact of the balls almost entirely spent.

Two cases which illustrate this occurred at the siege of Sebastopol. In neither did the clothing or the abdominal walls show any signs of injury, but in both the liver and spleen were comminuted to a pulp and the intestines extensively lacerated (Mr. Hulke, *Lancet*, December 31, 1892).

As yet we have no reports from surgeons of the armies engaged in the present strife between Japan and China, but it will be of great interest to read the records of such cases. We can expect, I think, a very full and detailed account from the Japanese surgeons. We have all applauded the work of some brilliant individuals of the Japanese profession, and, in fact, we must assign to Japan in medicine the same standing that she has taken in other walks of civilized life, and which she has demonstrated she can hold.

The most prominent symptom is pain, which is accompanied by shock, the degree of which is dependent upon the extent of

* Annual address before the Philadelphia Academy of Surgery, January 7, 1895.

† Professor of Surgery, Philadelphia Polyclinic; Assistant Professor of Surgical Anatomy, University of Pennsylvania; Attending Surgeon to the German and Philadelphia Hospitals; Consulting Surgeon to the Germantown, St. Timothy's and St. Agnes' Hospitals.

injury and the temperament of the individual.

I might say here that temperament and nationality have a strong bearing in the production of shock. Persons of a highly nervous temperament suffer more from shock than do phlegmatic individuals. For example, Americans are far more liable to suffer a severe degree of shock following injuries or operations than are the Germans.

The pain is peculiar and difficult to describe, but is readily recognized by one who has seen many of these cases and by the patient himself. It is not that of ordinary intra-abdominal affections, but is described by the patient as if something had given way or ruptured, and is usually accompanied by a consciousness of impending death. It is usually accompanied with tenderness, which will be more or less localized, unless the ensuing peritonitis be general. In the early stages of the injury, when shock is most profound, it may not be so pronounced, and if large doses of opium be administered it may be masked throughout the course of the trouble.

When vomiting is present it is usually associated with pain. Rarely does the vomited matter contain blood.

There is often seen a characteristic rigidity of the abdominal walls, which is due to intra-abdominal irritation. I have seen this so marked as to recall to mind the checker-board appearance of the normal abdominal walls as represented in the pictures of the early artists.

In the cases I have observed, consciousness has invariably been retained for varying periods of time. Restlessness is not usual in the early stages except in severe hemorrhage, but later on, when peritonitis develops, it is not an uncommon symptom.

The pulse and temperature vary according to the degree of shock. The former is weak and running, varying from 100 to 160, and the temperature subnormal. If reaction takes place the pulse becomes stronger and less frequent and the temperature reaches the normal line. After reaction peritonitis is invariably the rule, and is accompanied by an accelerated and a high-tension pulse. The temperature under these circumstances is unreliable, as it does not correspond to the degree of inflammation or septic infection. A high temperature with a slow pulse is less significant than a rapid pulse with a low temperature. In cases of septic peritonitis where autopsy revealed a belly cavity full of foul pus, I have seen the temperature run a normal course throughout the disease.

The part the sympathetic system of nerves, which has its largest distribution in the abdominal cavity, may play in injury to the abdomen is important in considering the differential diagnosis between the simple contusion and contusion accompanied by visceral lesion. In the former the absence of the severe and characteristic pain, of constant and persistent vomiting, of the anxious expression and presentment of impending death, and of any evidence of loss of blood, associated with the occasional presence of suddenly developed meteorism, will usually be sufficient to establish the differential diagnosis. This condition of meteorism is due to paralysis of the muscular coat of the bowel consequent upon the concussion of the plexuses. There are cases, however, where it is very difficult to say definitely whether there be a visceral complication or not. Under these circumstances one can only wait for a comparatively few hours, when, if improvement is not apparent, the operative course is to be pursued. When the solid viscera are the seat of injury hemorrhage will be the main source of anxiety. The pain and the exsanguination give the clue. If the patient should react, which is unusual unless the kidney is the injured organ, we will find, in addition, dullness on percussion in the flank. Rectal or vaginal examination may afford aid in determining the presence of a collection of blood in the pelvis. The solid organs suffer most from external violence on account of their fixity, density and close proximity to the bony structures. The liver is the most often injured, then the uterus, spleen and kidney, in the order named. The stomach is least often injured, there being very few such cases on record. Dr. J. W. Goff (THE MEDICAL AND SURGICAL REPORTER, 1892) reports a case of ruptured stomach following a horse-kick of the abdomen, verified by an autopsy. The shock was profound, and there was vomiting with absence of blood. The author states that he believes immediate operation would have saved the patient's life.

In the Glasgow *Medical Journal* for 1894, vol. xli, Andrews reports a case of rupture of the stomach without external evidence of violence, in which all the symptoms of a serious visceral lesion were present with the exception of vomiting. The rupture was upon the anterior wall, was about an inch long and involved all the layers. I cite this case as one of special interest on account of the location of the tear and the absence of vomiting.

The liver is the organ most often affected because of its position beneath the ribs and against the spine, and because it is held firmly in place by strong ligaments and blood-vessels. It is most commonly ruptured on its upper surface, generally in the right lobe, and in a majority of such cases the injury proves fatal. Dr. H. P. Loomis (*Medical Record*, January, 1893) reports a case where the patient was struck by a pole protruding from the back of a wagon, which, when the wagon turned the corner, struck him on the right side, leaving no external evidence of violence. There was a three-inch tear in the right lobe of the liver and a pint of blood in the abdominal cavity. The patient died in the street from hemorrhage before medical aid could reach him.

Mr. Battle (London *Lancet*, 1894) reports a case of rupture of the bile duct in a boy six years of age, who was run over by a hansom cab, in which there was but a slight shock without much pain or tenderness. Vomiting began early and persisted. On the fifth day slight jaundice developed. He was operated upon on the eighth day, and the abdominal cavity was found filled with bile. He died on the morning of the ninth day.

Autopsy.—Liver and gall-bladder were intact, but about one-half an inch beyond the junction of the cystic and hepatic ducts the common duct was found to be torn completely through. No other injury was found.

J. E., aged forty-six, was admitted to the German Hospital on November 17, 1893, suffering from injuries received by being struck by a locomotive. He had a compound fracture of the lower jaw, lacerated scalp wound and fracture of four ribs on the left side, with no other signs of injury. He died six hours later. Post-mortem examination revealed a hemato-thorax of the left side. The peritoneum was not perforated or otherwise injured, but the peritoneal cavity was filled with blood. The spleen was completely comminuted, and the left kidney had been forced from its bed and was floating in the retro-peritoneal space. There was an extensive hemorrhage between the layers of the mesentery, and a hemorrhagic extravasation of the posterior wall of the stomach.

H. M. C., colored, aged sixteen, was admitted to the German Hospital on the evening of December 3, 1894, with the following history: While playing about some moving freight cars he was accidentally caught between the bumpers, sustaining an injury to his abdomen. Examination upon admission failed to disclose any evidences of external injury. The introduction of the catheter drew clear urine. There was a moderate degree of shock, and the patient complained of severe pain in the abdomen and tenderness on palpation. Further investigation proved negative.

The resident surgeon, Dr. Page, not deeming the case of sufficient severity to send for me, treated the patient for shock. When I examined him upon the following day, it was very evident, from the severity of the abdominal pain and tenderness associated with very decided rigidity of the abdominal walls, that he was suffering from a serious intra-peritoneal lesion. I decided to open the abdomen at once. As soon as the peritoneal cavity was opened a large quantity of dark liquid blood escaped. The small intestines were delivered, when the cause of the lesion was found to be a ruptured mesenteric vein, the bleeding from which was arrested by the presence of a large diffused blood-clot occupying the interval between the layers of the mesentery. To make sure that there was no other lesion, the large intestines, the stomach, the liver and the spleen were carefully examined, but with a negative result. The abdominal cavity was washed out with warm saline solution, glass drainage was introduced into the pelvis and the wound closed. Recovery was uninterrupted.

L. C., male, Italian, aged thirty-five, was admitted to the German Hospital, with a history of a fall of about 50 feet, striking upon his abdomen. He was profoundly shocked and exsanguinated. The only external evidences of injury were some slight cuts on the hands and

head. A diagnosis of internal hemorrhage was made and the abdominal cavity opened up. Dark liquid blood escaped as soon as the peritoneum was opened, and the source found to be the mesenteric vessels. The mesentery was torn half-way across and the intestines lacerated in four places. The mesentery was united with a series of catgut ligatures. The rents in the intestines closed with the Lembert sutures. The abdominal cavity was washed out with hot saline solution and closed. He died two hours after the operation. The autopsy demonstrated several tears in the gut which had been overlooked and several grape-skins and pieces of fig in the peritoneal cavity.

The most common form of intra-abdominal hemorrhage is that resulting from ruptured extra-uterine pregnancy. While these cases may be due to traumatism without any internal evidence, they are usually spontaneous. While hemorrhage from the pelvic organs of the female usually occurs from a ruptured extra-uterine pregnancy, it may be due to other non-traumatic causes. Hematosalpinx may occur independent of pregnancy, and rupture either spontaneously or from traumatism. Again, degenerated blood-vessel walls, and especially veins, may rupture under similar circumstances.

M. E., aged twenty-four, nurse, admitted to the German Hospital January 20, 1893. While lifting a heavy weight from an elevator she felt something give way in her abdomen. This was immediately followed by severe lancinating pain in the right ovarian region. She was menstruating at the time. Pelvic peritonitis promptly set in. An examination demonstrated a tumor in the right broad ligament about the size of a hen's egg. The peritonitis and tumor subsided to treatment, and she made a slow recovery. Diagnosis, pelvic hæmatocele from rupture of an engorged ovarian vein.

Hemorrhage itself is seldom the cause of death, but associated as it is with shock, the degree of which is out of all proportion to the severity of the accident, it is frequently fatal in a very short time. When the peritoneum is wounded shock is still more profound, the so-called peritoneal shock.

Hemorrhage within the peritoneum is sometimes very slight and distinctly localized, and may occur several times during the course of the illness. It may take place between the layers of the broad ligament and soon stop from the pressure.

I report the two following cases of hemorrhage from my list of operations for ruptured extra-uterine pregnancies, as they illustrate so typically the wisdom of immediate operation:

Mrs. A. K., aged thirty-one, admitted to the German Hospital September 21, 1894, with the following history. Six months prior to admission she had been subject to attacks of vertigo, pain in the back and limbs, and for the last six weeks to a constant bloody vaginal discharge. Examination revealed a retroflexed uterus with a slight tear of the cervix and the presence of a small movable mass behind and to the left of the uterus.

September 25th, four days after admission, the patient was etherized and the uterus was dilated and curetted. After the operation the discharge stopped, but the patient gained in strength very slowly. She was advised to submit to abdominal section, but preferred to wait until she was stronger. On the night of November 22d she awoke with a severe pain in the right side, and on attempting to walk to the water-closet fainted. After being returned to bed she again fainted and went into a collapse, the pulse becoming almost imperceptible and the temperature falling to 96°. Under active stimulation she reacted. The diagnosis was made of internal hemorrhage from rupture of a probable extra-uterine pregnancy.

The abdominal cavity was found filled with fluid blood and clots and the right tube ruptured. The tube was tied off and the abdominal cavity flushed with hot saline solution, a glass drainage-tube introduced and the wound closed. The patient was not much shocked by the operation, but on the contrary seemed rather improved. The drainage tube was removed on the third day, the wound healed by first intention, and the patient made a good recovery.

Mrs. J. W., aged thirty-six, was admitted to the German Hospital November 21, 1894, with the following history. About two o'clock on the morning of admission she was seized with a violent pain in the lower abdomen. For this she took some whisky and was somewhat relieved. At nine o'clock the same morning she

started for market .and was suddenly taken sick, becoming very weak and suffering from a violent pain in her abdomen. She returned home with difficulty and called in Dr. Hand, who advised her immediate removal to the hospital. At the time of admission she was very weak, and there was distinct tenderness over the abdomen with slight dullness on the right side. Immediate operation was advised and consented to.

When the peritoneal cavity was opened it was found to contain fluid blood and clots. The right tube was the site of a small rupture and was tied off and removed. The abdominal cavity was washed out with hot saline solution, glass drainage introduced and the wound closed. The patient was very much shocked by the operation and reacted slowly. During the operation hypodermatoclysis was practiced. The drainage-tube was removed on the fourth day, the wound healed by first intention, and the patient was discharged, well, on the twenty-third day.

The following case of hemorrhage from ruptured extra-uterine pregnancy illustrates the danger of delay as strongly as did the two previous cases the efficacy of prompt interference:

Mrs. P., aged thirty, was a patient of Dr. S. Cooke Ingraham, of Wissahickon, this city, who furnishes the following history:

I first saw the patient on January 29, 1892. She complained of severe abdominal pains of a bearing-down character and of a sense of fullness in the epigastric region. She had been married seven years, but had never been pregnant and laughed at the possibility. For the past three years the menstrual flow had been decreasing in amount and for several months past had been very scant. The breasts were slightly enlarged, but the areolæ were not darkened. The glands of Montgomery were a little more prominent than normal. She had suffered from morning vomiting for the past month.

I was hastily summoned to see the patient on the morning of February 2d, and found her in a state of collapse, pulseless and with a temperature of 96.5°. She reacted to active stimulation and was sent to the German Hospital for immediate operation, a diagnosis of ruptured extra-uterine pregnancy of the tubal variety having been made. Upon admission her pulse and temperature were normal. She did not complain of pain. Examination of the abdomen and per vaginam and rectum failed to reveal any mass, although a circumscribed area of flatness could be demonstrated low down and to the right side. She continued in this condition until February 12th, when at her own request she was discharged. On February 23d she was readmitted at Dr. Ingraham's earnest request. At the time of the second admission the abdomen was markedly distended, being tympanitic above and flat below. Pulse 116, .temperature 101.5°. She complained of considerable pain.

The following day she was operated on, and when the peritoneum was opened a fetus with clots and fresh blood gushed out. The ruptured sac occupied the right iliac region and was tightly adherent to the neighboring coils of small intestines, to the cecum and to the vermiform appendix. After a prolonged and tedious dissection the sac was enucleated; this was accompanied by very free bleeding, which necessitated packing of the cavity with gauze. The wound was closed with the gauze packing *in situ*. The patient died the following day of hemorrhage.

The immediate effects of an injury severe enough to cause a serious lesion of an abdominal viscus are sometimes so slight as to be misleading. Very often a patient with such a condition will walk to a conveyance or to the hospital, complaining only of a slight pain. In varying periods of time following the injury more decided symptoms will develop, viz., signs of hemorrhage if the solid organs be involved and early peritonitis if the hollow viscera be ruptured or torn sufficiently to allow their contents to escape. When this occurs operation is imperatively demanded without delay. This is also true of hemorrhage consequent upon the rupture of an extra-uterine .pregnancy, be it traumatic or spontaneous. In ectopic gestation operation will be necessary in every case at some period of its history; therefore if a diagnosis can be made, or even a well-founded suspicion of the condition exists, rupture should not be allowed to occur. If rupture does occur, however, immediate interference is the only certain means of saving the patient's life. The longer the operation is deferred the greater the risk to life. Hasty operations,

often necessitated by the patient's condition, are likewise less liable to reach a favorable termination. Blood-clots or intestinal or gastric contents cannot be washed out of the peritoneal cavity except by prolonged and repeated flushing.

The almost universal fatality of intra-abdominal lesions of traumatic origin is so well recognized that it seems as if there could hardly be any question as to the wisdom of opening the abdominal cavity. I would not be understood as meaning that abdominal section should be used as a means of diagnosis, but on the contrary I believe that every known means, with attention to the most minute details, should be exhausted in establishing a diagnosis. When a diagnosis is impossible abdominal section is justifiable only when it becomes the last and only chance for the patient.

I have refrained from using the terms exploratory and diagnostic incisions, believing that they not infrequently serve as a shield to cover a lack of diagnostic ability. It is a moral obligation resting upon every physician and surgeon to develop to the utmost of his ability the highest diagnostic attainments.

Aseptic surgery has undoubtedly been one of the greatest boons to humanity that this nineteenth century has brought forth. But to me it seems that it affords a great temptation to men who have not had experience and surgical training, and who have, therefore, not fully developed their diagnostic skill, to do operations which are not necessary for their patients' good or with a scientific precision.

A CASE OF MALPRACTICE.

P. J. FARNSWORTH, M.D., CLINTON, IOWA.

The Spitz dog of a highly respectable family of this city had a difficulty with his throat. Respiration impeded; deglutition difficult. The carriage was ordered out and Tip was taken to a leading surgeon. The latter diagnosed stenosis or tumor of the larynx in the neighborhood of the vocal cords, as Tip's bark had sailed away and was lost at C.

An examination confirmed this diagnosis, and under chloroform an operation was performed. The dog died. At post-mortem examination it was found that some one had slipped over his head a rubber band such as druggists use to tie up packages. It had worked through the hair and bedded itself in the skin. In any case it was the cause of the dog's death, and the bereaved are now querying where to fix the blame.

DEATH FROM URETHRAL INJECTION OF COCAINE.

In this case the patient was aged seventy-two, with heart disease, atheromatous arteries, and subject to angina pectoris. He had also an enlarged prostate, which caused retention. Attempts at catheterization failed, and puncture was resorted to. The next day catheterization having again failed, suprapubic cystotomy was decided on; but a last attempt was made to pass the catheter under cocaine. Twenty grams (!) of a 5 per cent. solution was injected into the urethra. Immediately the patient became pale, general trembling set in, he sat up in bed, commenced to vomit and fell back dead.

In a report on the case Dr. Reclus says that, remembering the absorptive power of mucous membrane, it is not surprising that one gram of cocaine injected into the urethra should cause death, and the large quantity employed was the sole cause in this case. It had already been said down that 15 to 20 centigrams should not be exceeded, and that the solution should not be more concentrated than 2 per cent. It was also pointed out that the recent injury done to the urethra would largely contribute to the rapid absorption that evidently took place.—*La Sem. Med.*

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

SALICYLIC ACID BY THE RECTUM.

Dr. Erlanger (*La France Médicale*, No. 1, 1895) from experiments on a large number of rheumatic patients at the Munich Hospital, finds that one may employ rectal injections of solutions containing salicylic acid with advantage in treating this disease. Absorption, he has observed, is somewhat slower by this method, though the results are as satisfactory as when given by the mouth. He sets forth the following rules for its administration:

The rectum should first be emptied by a preliminary injection; the solution should be lukewarm. The most convenient formula is the following:

Salicylate soda.....	6-8	o	ʒ jss-ij
Tr. opium.	1	o	gtts. xv
Water.....	100	o	ʒ iij ʒ j

The solution should be thrown high up into the bowels by means of a rubber œsophageal sound attached to a syringe. The patient must be instructed to retain the clyster.

TREATMENT OF SYPHILIS IN CHILDREN.

Dr. J. Simon (*Revista de Ciencias de Medicas de Barcelona*, No. 23, 1894) with regard to prophylaxis, recommends advising against matrimony in subjects with contagious primary and secondary symptoms; to require a free after-period of at least twenty months, during which there are no visible syphilitic symptoms; to prohibit marriage in those with rebellious tertiary symptoms with visceral lesions. During the pregnancy of syphilitic mothers, administer mercury in small but continuous doses. Recommend nursing energetically, for "a woman who has brought forth a syphilitic child will not be infected by her child during nursing" (Colles' law). In case of impossibility, seek a syphilitic nurse, but never give it to one who is healthy. In case of necessity feed with mother's milk by the bottle. In children of five to six weeks, give during the day Van Swieten's solution, 20 gtts. four times a day in milk. At the same time give inunctions of mercurial ointment (0.50:2.) morning and evening. One inunction a day will, however, suffice. On going to bed is the best time. Change the regions where applied from one side to the other. This treatment should not, as a rule, last longer than four weeks. The dose of Van Swieten's solution may be decreased, increased or interrupted from time to time. Indirect treatment may be instituted by administering the mercury to the mother or nurse. If she be syphilitic, then give her the iodide of potash and apply mercurial ointment by inunction to the child. In case of protuberant osseous tumors, apply Vigo's plaster. Separation of an epiphysis requires fixation in an immobilizing bandage until consolidation takes place. If it has completely separated from the rest of the bone, then remove it as if it were a foreign body.

FRESH MEAT-JUICE IN DISEASE.

Professor v. Ziemssen (*Wiener Medizinische Presse*, No. 52, 1894), the celebrated clinician of Munich, speaks very highly of freshly expressed meat-juice as a food in disease. Those patients who find the bloody taste repugnant, may easily have this disguised by adding a little brandy and extract of vanilla with sugar, and upon freezing it an agreeable ice-cream is formed which is eaten by the most fastidious with pleasure. In this manner administered there will be no difficulty in giving a patient at least 200 grams (ʒ vjss) of the juice, and, indeed, even to those patients who have a disgust for all other forms of food or who cannot retain food, as typhoid cases.

CHLOROFORMIZATION BY THE DROP-BY-DROP METHOD.

Dr. C. G. Bremer (*Vratch*, No. 52, 1894) communicates the results of his experience with the drop-by-drop method in administering chloroform as an anesthetic in 1,000 cases. He concludes that anesthesia is much less disagreeable for

* In charge of the translator, F. H. Pritchard, M.D.

the patient; excitement is less frequent; the patient comes more quietly under the influence of the anesthetic, and vomiting is less frequent during its administration. The quantity of chloroform required for complete anesthetization of an adult, is between 17.5 and 21.5 grams instead of 100–200 grams as by other methods. He has found that the anesthetic may be continued for several hours without danger; vomiting, headache and other disagreeable symptoms following awakening are less frequent, while accidents are infrequent.

STROPHANTHINE.

Professor v. Ziemssen (*Muenchener Medicinische Wochenschrift*, No. 50, 1894) says that strophanthine, though not so lasting in its action as digitalis, is preferable to the tincture of strophanthus as a substitute for digitalis; both, in the tincture, had best be cast out of the Pharmacopœia on account of their unreliability. Digitalis he would have used only in infusion or powder. Strophanthine is not cumulative in its action. He administered it in a dose of 0.001 (1/60 gr.) twice a day.

OINTMENT OF RED OXIDE OF MERCURY IN VARICOSE ULCERS.

Dr. H. Langes (*Muenchener Medicinische Wochenschrift*, No. 48, 1894) speaks highly of treating varicose ulcers of the legs with an ointment of the red oxide of mercury. The officinal ointment he has found to be too strong (one part of the red oxide of mercury to nine of vaseline), so that he mixed it with one to two parts of vaseline. The influence upon suppurating wounds was apparent in a short time, not only upon suppuration, but also upon the development of healthy granulations. The first day the patient usually complains of violent pains, which by the third have entirely or nearly disappeared; at the same time the bottom of the ulcer will assume a healthy appearance and vigorous granulation and cicatrization will follow. With the mixed preparations of the ointment the reaction was less violent, but healing also took place, but less rapidly. The dressing should be renewed once a day and the salve be spread upon a piece of cloth to the thickness of a knife blade; a flannel or small bandage may be used to wrap the extremity. Rest in bed will accelerate the healing process.

TREATMENT OF TAPEWORM.

Professor Potain (*L'Union Médicale*, No. 30, 1894), in a lecture on the tapeworm and its treatment, among the long series of remedies which have been proposed finds but few which are actually reliable. They may be divided into indigenous and foreign; among the latter are kousso, musenna and kamala. Kousso is an excellent remedy, but it is so easily altered that it is of not much practical value. The male fern, an indigenous remedy, is especially employed in expelling the bothriocephalus. The ethereal extract is used as well as the powder and the decoction. One may administer 2 grams (grs. xxx) of the ethereal extract mixed with 3 grams (grs. xlv) of the powder, after which one may take a decoction of 3 grams (grs. xlv) of the powder in 100 grams (℥ iij ʒ j) of water. Two hours after 2 ounces of castor oil are given. In certain cases pumpkin seeds will yield good results; those of the cucurbita maxima are best used, as the smaller varieties are harder to obtain and give less satisfactory results. Take 250 grams (℥ viij) of the seeds, which after extracting the kernels will leave about 50 to 60 grams of hulled seeds. These are rubbed up with sugar to form a paste, or with milk to make an emulsion. The evening before the patient should be put upon a milk diet and the seeds ingested the following morning. Two hours after follow with a purgative. Squash and gourd seeds are only indicated in individuals with susceptible digestive tracts; they will yield but uncertain results.

The true and most efficacious remedy is the bark of the roots, trunk and young branches of the pomegranate; the dose is 60 grams (℥ ij) of a not too old bark, which is macerated for twenty-four hours in 750 grams (℥ xxiijss) of water, which is later reduced by slowly boiling to 500 grams (℥ xvss). This should be taken in two portions, with an interval of ten minutes, and then followed with 60 grams (℥ ij) of castor oil as soon as the patient feels a little motion in the abdomen. If the oil be given too early, the worm will not have been stupefied; if too late the head will remain. This drug may cause vertigo and

roaring in the ears, which symptoms are still more prominent with pelletierine, a glucoside extracted by Tanret. The sulphate is usually employed, but it has the inconvenience of being absorbed by the stomach and in acting upon the patient and not upon the worm; therefore Tanret has mixed it with the sulphate of tannin to retard absorption. The patient, from the evening before having been upon a milk diet, takes 30 cgms. (grs. ivss) in two doses, with a half-hour of interval; then after about an hour a purgative is administered. If this does not act, a purgative rectal injection is indicated. Out of 100 cases, one will obtain successful results in about 79. This alkaloid also gives rise to vertigo, roaring in the ears and a sort of very marked "drunkeness." All these symptoms will be less intense if one take care to keep the patient in bed. In case of failure do not repeat the remedy until the sections reappear in the stools. It seems, in some cases, as though the worm became accustomed to this drug.

A CASE OF TETANUS IN A PREGNANT WOMAN.

Dr. Augustin (*Spitalul*, No. 17, 1894) recently reported the case of a woman who, in the seventh month of pregnancy, suddenly developed tetanus after taking cold, and who was cured spontaneously in a month. Pregnancy was not interrupted, and she was delivered of a healthy child at full term. He proposed premature labor, but she refused and was taken from the hospital after receiving a few rectal injections of chloral and the bromide of potash, together with two hypodermics of pilocarpine. At home, in the country, she recovered without any treatment beyond rubbing her head with brandy. He calls attention to the possible gravity of this disease for both mother and child.

FEVER OF TUBERCULOSIS IN CHILDREN.

Dr. Rachford (*Covremennaya Klinika*, No. 10, 1894) in treatment of the fever of tuberculosis, and particularly that of the lungs, in children, advises the following salve:

Guaiacol	āā	4	o ʒj
Lanoline			
Lard		30	o ʒj

Rub a little of the salve of the size of a hazel-nut into the region of the chest each evening.

TREATMENT OF NEURALGIA.

Professor Dujardin-Beaumetz (*Revue Internationale de Médecin et de Chirurgie Pratiques*, No. 17, 1894) recommends the employment of antipyretics which are at the same time analgesic. Phenacetine may be given in doses of ½ to 1 gram (grs. vijss–xv) in two to three powders in twenty-four hours. In migraine, antipyrine is to be preferred; in lightning-like pains, pains from pressure and pains of dental origin, give acetanilid. In essential neuralgia, exalgine is preferable. Phenacetine is of greatest service in the painful affections of neurasthenic and neuropathic subjects. Antipyrine may be administered in doses of 1 to 4 grams (grs. xv–ʒj) in twenty four hours, either in powder or in a grog. The fulgurant pains of tabes are best controlled by acetanilid. Give 1½ grams (grs. xxijss) in three powders during twenty-four hours.

BICHROMATE OF POTASH IN GASTRIC AFFECTIONS.

Professor Fraser (*ibid.*) has employed bichromate of potash in 18 cases of simple dyspepsia, and 10 cases of ulcer of the stomach, in doses varying from 5 mgms. to 1 cgm. (1/12 gr: 1-6 gr.) three times a day, either in pill form or in a watery solution to which has been added a little syrup of tolu or orange and taken before meals. A few days after its use, all the dyspeptic symptoms, the pains, nausea, vomiting, etc., decreased in severity or disappeared completely. He rather ascribes the results to a particular action upon the gastric mucous than to any antiseptic influence.

INDICATIONS FOR COLD BATHS IN DISEASES OTHER THAN TYPHOID.

Dr. Wiart (*Gazette des Hôpitaux*, No. 50, 1894) sets forth the following indications for cold baths in various diseases, not including typhoid fever:

General indications—

1. When the urine is scanty, dense and charged with albumin.
2. When there is elevation of temperature.
3. When there are grave nervous symptoms even without high temperature.

4. When the heart is failing.

Special indications—

1. In erysipelas and particularly in the severe and typhoid forms. Cold water will not arrest the course of the disease, but it will calm the pains, reduce the nervous symptoms and shorten the period of convalescence. Renal complications give a second indication especially.

2. Small-pox is a disease where writers disagree as to indications. Vinay and Juhel-Renoy administer cold baths from the beginning, thus claiming a decrease of severe symptoms and find no contraindication in the eruption. But Vinay, after suppuration commences, only employs a bath of 28° C. Clement only begins to give baths at this period. In the hemorrhagic form the results were nil; in the confluent and coherent varieties the mortality was lowered.

3. Scarlet fever in the adynamic or atonic forms is only to be treated by cold baths. Renal, cardiac, pulmonary, articular and hemorrhagic complications do not contraindicate.

4. Measles are only to be treated thus in the anomalous forms.

5. Pneumonia and broncho-pneumonia in France are thought only exceptionally to be treated by cold baths. In children, when the general symptoms become serious, they will possibly sustain the patient and lower the temperature, yet they are not curative measures.

6. In cerebral rheumatism in the acute form it is the only efficacious treatment; in the apoplectic variety it is without effect. Put the patient into very cold baths, repeat them frequently and prolong them; massage energetically and give alcohol in generous doses. Thus one may lower the temperature from 42° to 37° C. in forty-eight hours. Montagne and Amblard have also treated cerebral gout with high temperature by cold baths with success.

7. Puerperal fever requires the cold bath in the acute septicemic forms with typhoid symptoms.

8. Exanthematic typhus, when there are high temperature and general nervous phenomena, necessitates these measures.

9. Finally, cold baths have been employed with success in grippe in a malignant form, tetanus, infectious icterus, hepatic colic with profound adynamia, and nephritis.

IS THE BABY TONGUE-TIED?

Dr. Chervin (pamphlet, Paris, 1894), the director of the Institute for the Treatment of Stammerers at Paris, has made an interesting study of the surgical aspect of this subject. Much performed in certain regions of France and formerly often done by some of the greatest surgeons, he thinks that its use has a very limited application; for example in those rare cases where the tongue is bound down to the floor of the mouth by an inferior ankyloglossia so that the tongue is immobilized. In certain cases where the frenum is too long and by extending even to the tip of the tongue interferes with nursing, then not a mere incision, but an excision is required. This is exceptionally necessary, and though in itself insignificant, it may present serious danger in a little child. It is wrong to think that if an infant nurses badly its frenum must be cut. A little exercise upon the end of one's finger will correct this fault and operative interference will be unrequired. Cutting the frenum is absolutely useless in correcting defective pronunciation, for this is only to be remedied by a methodic education of the voice by natural and rational exercises which will not exceed three weeks.

OBLITERATION OF THE SUPERIOR VENA CAVA AND ITS TREATMENT.

Dr. F. Merlin (*La Loire Medicale*, No. 4, 1894) records an interesting case of a man of thirty-four years, who presented all the classic signs described by Oulmont as characteristic of obliteration of the superior vena cava—œdema of the face, neck and upper portion of the thorax, but which was less marked in the arms; cough and attacks of dyspnœa, cyanosis, vertigo, headache and signs of cerebral congestion. He was put upon antisyphilitic treatment, 4 grams (ʒ j) of the iodide of potash a day, with local application of iodine to enlarged glands at the root of the neck behind the sternal fascia. Though the patient denied having had syphilis, the result confirmed the suspicions which were verified later. In one month all the symptoms were relieved; the œdema, cyanosis, dyspnœa and the accompanying deafness were cured and remained so definitely, as the writer was able to observe four years later.

INSUFFLATION OF AIR IN TUBERCULOUS PERITONITIS.

Dr. Folet (*Le Nord Medicale*, December 15, 1894) treated a case of tuberculous peritonitis with ascites by puncture, evacuation of six quarts of serous fluid and insufflation of three quarts of air, which method had been proposed some time ago by Mosetig Moorhof, of Vienna, with the difference that this writer advised injecting filtered air, while in the former case the air of the room was insufflated unfiltered. A recovery followed which has endured for nine months. It has been suggested to employ a similar procedure in tuberculous pleurisy.

TREATMENT OF ANGINA PECTORIS FROM TOBACCO.

Dr. J. Crook (*Le Semaine Medicale*, No. 1, 1895) recommends for the treatment of angina pectoris in tobacco-users, the following preparation:

Alcoholic solution trinitrine, 1 p. c.			gtts. xv
Fl. extr. cactus grandiflorus.	8	o	ʒ ij
Hoffmann's anodyne.....	2	1	ʒ v gtts. xv

Sig.: Thirty drops three times a day in a little water.

If necessary the dose may be increased gradually to sixty drops.

IODINE AND SALICYLIC ACID IN DIPHTHERIA.

Dr. Kersch (*La Semaine Medicale*, No. 1, 1895) claims as good results as with the antitoxine treatment, with the following formula in diphtheria:

Iodide sodium.....	3	o	grs. xlv
Salicylate soda.....	5	o	ʒ ji-4
Water.....	200	o	ʒ vj ʒ ij
Raspberry sirup.....	30	o	ʒ j

Sig.: A tablespoonful or two, if there is great urgency, every hour.

Out of 17 cases treated thus he lost 3. He excludes 2 cases where treatment commenced when there was intense cyanosis with orthopnœa and cardiac weakness. Under the influence of this treatment the false membranes were rapidly thrown off, and they gradually ceased to reappear. There is no danger of serious iodic symptoms.

A New Operation in Internal Hemorrhoids.

Dr. Janes (*Provincial Med. Jour.*) reports a new method for treating internal hemorrhoids by means of a clamp and suture instead of the cautery. After divulsing the sphincters he seizes each hemorrhoid and applies the clamp to its bone, cuts away the pile and approximates the mucous membrane of the stump with catgut sutures as follows: The ligature is threaded with two needles. Beginning at one end of the wound, one needle is made to transfix each side of the mucous membrane; then by means of a double continuous suture the surfaces are united with a cobbler's stitch, and in addition each time the needles are drawn through an overknot is tied. This form of suture is unique, as it prevents any possible bleeding and greatly lessens the risk of the deeper part of wound becoming infected.

Flatulence.

For flatulence in children Ringer recommends:

Tinct. asafœtidæ.....	fl ʒ ss
Aq. destill.....	fl ʒ ij

M. Sig.: A teaspoonful every hour or two.

For flatulence due to fermentation:

Acidi sulph.....	fl ʒ jss
Syr. zingiberis.....	fl ʒ vjss
Aq. destill.....	fl ʒ j

M. Sig.: A teaspoonful.

Influence of Habitual Inclination of Pelvis on the Pelvic Canal.

Hirst (*University Medical Magazine*) points out that although the pelvic obliquity on account of its normal variations can generally be neglected in regard to childbirth, the influence of habitual inclination of the pelvis on the development of the pelvic bones and pelvic canal has been neglected. Exaggerated inclination of the pelvis in childhood so that the trunk weight is received by the sacrum increases the forward rotation of that bone, diminishing the antero-posterior diameter of the inlet and the depth of the canal, while excessive action of the rotator muscles of the thigh tends to widen the outlet. On the other hand, if the pelvic inclination is diminished, the top of the sacrum is pushed backward, the antero-posterior diameter of the inlet is increased, as is also the depth of the canal; while pull on the ilio-psoas muscles, separating the iliac bones apart, and by compensatory displacement of the ischia, narrows the transverse diameter of the pelvic outlet.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, FEBRUARY 9, 1895.

EDITORIAL.

THE CHOICE OF AN ANÆSTHETIC.

The precise clinical value of any anæsthetic is settled by the practitioner or clinician and not by the experimenter. Unfortunately for the profession, the controversies as to the relative values of the different anæsthetics and which should be the one of choice from the standpoint of both safety and effectiveness, is largely due to uncertain utterances coming from laboratories. The relative clinical merits and demerits of the anæsthetic agents commonly in use, have long since been settled by active surgeons.

The early and free general use of chloroform resulted in precise knowledge of its risks and its great value in the hands of trained surgeons. Chloroform was and is safely used by trained anæsthetizers. Accidents, which are not common, are usually due to culpable carelessness and ignorance. The general, almost exclusive, use of chloroform by two of America's most prominent surgeons, Gross and Hunter McGuire, should go farther in settling the problem and should have more weight than the opinions of all mere experimenters whose notions, not experiences, find conspicuous place in medical literature.

The surgeon who knows it, and uses it night and day in the most difficult operations, has a right to speak plainly as to its great value, for he voices the lessons of his own work, the results in his own professional experience.

The laboratory practitioner, destitute, as he usually is of clinical and applied knowledge, is not a reliable authority, and in many instances has worked mischief. It is the man who has done and does put an anæsthetic to repeated practical tests, who can speak with the best authority.

Smothering cats or dogs with either chloroform or ether, paralyzing heart or respiratory centres; or water-logging kidneys or lungs in the human subject, is not surgical anæsthesia. Animal experimentation does not furnish a safe guide, for

here the anæsthetic is pushed to the point of death, or, where not, the conditions maintained furnish little of value in the line of surgical teaching. Any anæsthetic that deadens sensation, or paralyzes the respiratory or circulatory centres, if ignorantly or carelessly pushed beyond perfect anæthesia, will kill.

Chloroform may be, and has been used for prolonged and complicated operations in feeble, exhausted and anemic patients, without accident or unfavorable results. Commonly ether also can be prolonged without working mischief. Facts demonstrate that the lack of clinical knowledge prevents their absolutely safe use. About all recorded accidents, and the very many unrecorded, have been largely due to ignorance and inexperience. The number of deaths ultimating from the use of ether is probably greater than that of speedy deaths occurring from chloroform. A number of the deaths occurring in the first five or ten days following an operation, from pneumonia, edema of the lungs, suppression of the urine, etc., are directly chargeable to a reckless use of ether. Rarely is anything said about the anæsthetic being the primary cause. The timid apprehension of the profession favors the use of ether. It dreads accidents and still more that censure, professional and from without the profession, which follows sudden death. It must be granted that sudden death often occurs aside from the anæsthetic; shock, hemorrhage and other conditions must be taken into account. The profession knows perfectly well that chloroform kills quickly.

There is, in certain sections of our country, a very strong prejudice against chloroform, arising largely from the fact that the administration of the anæsthetic very frequently falls to the hands of untrained, inexperienced and incompetent men, thus greatly augmenting the risks. A surgeon who wishes to avoid anxiety must put either chloroform or ether in the hands of an experienced and thoroughly competent anæsthetizer. To be such requires long experience. A patient once under its influence can be kept safely for an hour with from two or three ounces of ether. Where complications accompany surgical conditions, many of our most successful surgeons make ether their choice, and find its administration by cautious and trained hands absolutely safe.

It is generally accepted that the surgeon should use that anæsthetic with which, in his practice, he has grown most familiar, and in the use of which he has had immunity from accident. Statistics in this connection are not reliable. In discussing the subject, Dr. Hunter McGuire, of Richmond, Va., who held an eminent position in the Southern army, and to-day is equally eminent among the surgeons of our country, says, in answer to the statement that statistics show that chloroform kills one in three thousand; ether one in ninety thousand: "We have no data or figures by which we can make such statements as to the number of deaths from chloroform and ether, and the number of times each anæsthetic has been given. So far as I am personally concerned, I think chloroform is safe as a rule, but we should select our cases. I venture to predict that when the experience of the civilized world is collected and analyzed, it will be found, if indeed it is possible to definitely settle such a question, that in certain cases ether should be given, and in certain other cases chloroform should be employed, and that every good surgeon will be expected to exercise discrimination in the selection of his anæsthetic. For myself I am wedded to neither of these agents. In general terms, in feeble, anæmic people, those suffering from the prostration of shock or loss of blood, I prefer ether; in either the young or the old, or in cases where cardiac, renal, or pulmonary trouble is suspected, as a rule I think chloroform is safer. That both agents sometimes kill the patient, the

most bigoted and partisan advocate of either ether or chloroform must admit. But which of the anæsthetics is more dangerous and apt to kill, is the paramount but undetermined question. I know I am within bounds when I say I have given chloroform 12,000 times; I give ether too. I think every good surgeon should select his cases. No one has a right dogmatically to give one or the other anæsthetic."

Bearing upon the subject we quote from Dr. Hamilton's "Legal System of Medicine."

"Ether the Anæsthetic of Choice.—We must be forced to the conclusion, in making selection of an anæsthetic, that ether, where it can be employed, is the anæsthetic of choice. Since Wunderlich has shown that the immunity from renal sequellæ formerly supposed to exist in chloroform narcosis has no foundation in fact, the last argument in favor of the employment of chloroform in place of ether, when the latter is not positively contra-indicated—as, for instance, by actually existing pulmonary conditions or in intracranial operations, in which class of cases ether seems to increase, while chloroform decreases the cerebral congestion; and in certain operations about the mouth and face where the galvano or thermocautery must be used or the mask frequently removed in the progress of the work—falls to the ground, when statistics showing the unquestioned safety of this anæsthetic agent as compared with chloroform are considered.

"A collection of yearly reports of narcosis covering 62 reports, making a total of 61,526 cases, shows after the deduction of 11,464 cases of nitrous-oxide anæsthesia, that there were 11 deaths in the remaining 50,062, or one in 4551 cases.

"The number of cases of anæsthesia collected during the past three years amount to 161,800, in which number there were 52 fatal cases, or one death in 3111 cases. Of 133,729 cases of chloroform anæsthesia there were 46 deaths, of one in 2907 cases. In 14,646 cases of ether narcosis there was not a single death. Of mixtures of chloroform, ether and alcohol (Billroth's) show in 3440 cases no fatality. In 4555 cases of bromide-of-ethyl anæsthesia there occurred one death. Of 597 cases of pental anæsthesia 3 were fatal.

"To sum up, therefore, it may be said that every patient to whom an anæsthetic is administered takes thereby some risk, but that this risk is less in ether than in chloroform narcosis. Each possesses especial advantages, but those claimed for chloroform relate chiefly to convenience, while those claimed for ether relate to comparative safety. The warning signals of approaching danger in ether can be recognized before the patient is beyond recall; in chloroform he is frequently already within the valley of the shadow of death before the anesthetizer is aware that anything is wrong. The surgeon, therefore, who at the present day selects chloroform as the anæsthetic of choice would do well to fortify himself with facts to show that ether is contraindicated in the particular case; otherwise the accusation may be made that an unnecessary risk was assumed in employing chloroform rather than ether, the patient dying from indubitable chloroform narcosis.

"More skill is required to produce ether narcosis than chloroform narcosis; more skill is required, also, to prevent the patient from dying from chloroform than from ether. An indifferently skillful anæsthetizer can easily kill a patient with chloroform, but he will not be able to anæsthetize properly with ether, much less destroy the patient without some warning which the operator himself would be likely to observe. With blood before him of a healthy hue, and the rhythm of regular and full respirations in his ears, the latter will feel safe as he proceeds in his work, if ether is used. Either of these failing, a word of caution to the anæsthetizer suffices to correct the undesirable condition. But if chloroform is employed the experienced operator knows only too well that the dark blood and absence of respiration mean that the heart has failed in its action, perhaps for several seconds or a considerable fraction of a minute before the dark blood and failing respiration occurred, and from this time on the most vigorous efforts must be made, with the chances greatly against him, to rescue the patient from death.

"Frequent attempts to punish surgeons for deaths occurring while an anæsthetic is being administered tend to damage, not only the profession, but society at large. The great benefit which humanity has received from the use of these agents has been in danger of being nullified by fear on the part of the administrator, not only of damage to his professional reputation, but of being punished as well. Owing to the difficulties of excluding other causes of death in a particular case, fatal narcosis is not easy to establish. This is particularly true where the operation has advanced sufficiently far to allow the element of shock to enter into the case. Reflex irritation of the cardiac centers, giving rise to lessened force combined with acceleration and intermittency, this eventuating in the arrest of the heart's action occurs especially when chloroform is administered. The sudden breaking up of adhesions within a joint, or dilatation of the anal sphincters has not infrequently been followed by the development of dangerous symptoms. Where the element of shock enters largely into the condition there can be no question as to the freedom of the surgeon from responsibility in the sudden collapse.

"Renal affections may result from either chloroform or ether. Contrary to what has been generally supposed, Wunderlich has shown that the latter agent is not alone in its supposed damaging effects upon the kidneys From his extended observations of the effects of the two anæsthetics upon the renal organs, he makes the following deductions: (1) An already existing albuminuria is often increased by etherization. (2) Albuminuria can be caused by narcotization with both chloroform and ether, but more frequently with chloroform. With the latter this resulted in 11.5 per cent. of the cases, with ether it occurred in only 6.9 per cent. (3) Casts appeared in the urine after both chloroform and ether, but more frequently following the former. This occurred after chloroform in 34.8 per cent. of the cases, and followed ether in 24.6 per cent. of the cases. (4) When casts are already present, both ether and chloroform have the effect of increasing the number. It follows, therefore, that both anæsthetics must be used cautiously, as both have the power of setting up degenerative changes in the renal epithelia.

"According to Bardeleben, excitement and fear before and during the administration of the anæsthetic do more harm than the latter, whatever its nature.

"When accusations are made that unusually large quantities of the anæsthetic agent have been used it would be well to bear in mind Mair's statements bearing upon this point. The author states that patients have inhaled 160 grams of chloroform in seven hours; 1023 grams in twenty-four hours in another case; in another, suffering from tetanus, 700 grams in twenty-four hours; in another 1000 grams in twelve hours; a woman in the puerperal state remained chloroformed for thirteen hours, 200 grams being used."

ABSTRACTS.

RECENT VIEWS ON SEA SICKNESS.

In a review of this subject by Dr. Skinner (New York *Medical Journal*) the author comes to the following conclusions:

1. The principal symptoms of naupathia result from the lowering of the patient's arterial blood pressure. This is a condition sine qua non of their development.

2. Seasickness in a person otherwise healthy and not too aged is promptly curable in the vast majority of cases.

3. Even in aged persons, or in persons having certain affections of the circulatory apparatus, there is often amelioration of the general condition by the employment of the new method of treatment.

4. The treatment consists in the hypodermic injection of from half a milligramme of atropine sulphate, associated with a milligramme of strychnine sulphate (or nitrate) dissolved in a cubic centimetre of distilled mint water.

5. The administration of these eminently toxic substances demands a great degree of attention, prudence and supervision on the part of the physician, who alone should be the judge of the opportunity of their administration and of their dose in each individual case. Given at proper times and in suitable doses, however, no harm whatever will follow their administration.

6. The sympathetic nervous system plays a preponderating role in the causation of naupathia.

7. Naupathia, or seasickness—an affection without known anatomical lesions, and of which the predominant symptoms have their origin in the nervous system, and especially in the sympathetic or ganglionic nervous system—ought to be regarded as a neurosis of the sympathetic.

8. This neurosis may recur during the course of a long voyage, but each attack is almost always amenable to the same treatment.

SALOPHEN IN DISEASES OF CHILDREN.

Dr. Richard Drews (*Allg. Medecin. Central-Zeitung*) has treated with salophen 15 cases of acute articular rheumatism in children varying from 7 to 14 years. In 5 cases one or both knee-joints were affected, in 4 both ankles, in 4 both shoulder joints, and in 2 all the joints of one side of the body. The remedy was administered in accordance with the age in doses of 0.3 to 0.5 gm. every 2 hours, and 3.0 to 5.0 gm. pro die, and in no instance was any influence upon the heart noted. In the majority of cases the pains were already relieved on the first day and vanished completely at the end of 3 or 4 days; the temperature always fell to normal in the course of 3 or 4 days coincidently with the subsidence of the swelling. In 12 out of the 15 cases profuse perspiration occurred about half an hour after the exhibition of salophen which, however, had no effect upon the general condition. Aside from this no after effects of any kind were observed. An extension of the affection from one joint to another did not occur; in 2 cases, however, 3 or 4 days after subsidence of the swelling a recurrence ensued which again disappeared after 3 days' use of the remedy. Salophen therefore has the same effect in acute articular rheumatism as salicylate of soda, while free from its unpleasant sequelæ, such as gastric disturbances, tinnitus, vertigo, cardiac depression. An equally satisfactory result was obtained in 5 cases of severe acute muscular rhematism of the muscles of the neck in which a cure was effected at the end of 3 days. In a case of purpura rheumatica in a girl of fourteen years old, salophen in 0.5 gm. doses every 2 hours also had a favorable action upon the pains, fever and eruption. A

case of chorea is reported in which under administration of 5.0 gm. doses pro die for 12 days the choreic movements, as well as a coincident systolic murmur, disappeared completely. As an antipyretic salophen proved serviceable in various febrile diseases, typhoid fever, scarlatina, pneumonia, tuberculosis, acute tonsillitis, the temperature being reduced 1.5 to 2 degrees C. in the course of half an hour. As an antineuralgic it acted admirably in a number of cases of migraine in children varying in age from eight to thirteen years, the pains being completely relieved by 2 or 3 doses of 0.3 to 0.5 gm. On the ground of his experience Drews therefore concludes that salophen is an excellent remedy in acute articular rheumatism, deserving preference over all other drugs in pediatric practice, that it is a useful antipyretic and an excellent antirheumatic. It was always well borne, and being tasteless can be administered without difficulty.

BOILING WATER—TREATMENT OF SURGICAL TUBERCULOSIS.

This treatment which was originated by Professor Jeannel about one and one half years ago, has since been employed by him with success, in cases of surgical tubercular disease, comprising ulcerations and abscesses of soft parts, as well as lessons of the bones and joints. Dr. Bauby, Professor Jeannel's *chef de clinique*, describes the procedure as follows: When one has to deal with an abscess of the parts or a lesion of the bony tissue, the tubercular focus and the fistulous canals are opened, and in an operable case of tubercular affection of the joints, typical resection is first performed. All the caseous products and granulations are carefully removed with the curette, the cavity is sponged out, and the blood completely staunched. In the meantime salt water has been kept boiling in a can of some sort (coffee-pot, tea-kettle or samovar), provided with a long spout or faucet, to which is adapted a long rubber tube with a pointed stopcock at its other free end. The jet is then turned on and, after the first contents of the tube have been allowed to run away, in order to heat the latter, the tubercular cavity is filled up with boiling water. The water is removed by sponging, after which the cavity is again filled with boiling water and emptied anew. This process is continued until the surface has been sufficiently cauterized.

A better procedure of boiling water treatment consists in pouring into the cavity cold or tepid water, and then heating it to the boiling point by insertion of the red-hot point of the thermocautery, the heat being maintained by continuously working the *pump*. One minute is sufficient to boil in this manner the water contained in the abscess, the size of a pigeon's egg. The water rapidly evaporates, leaving the cavity nearly empty. This process is repeated four or five times in succession. It is hardly necessary to say that, whichever method of boiling water treatment be employed, general anæsthetization is indispensable, except in cases of very small abscesses, in which cocaine anæsthesia may suffice.—*Med. Week.*

For Acute Coryza.

The *Medical Fortnightly* gives this formula for acute coryza:

Morphinæ sulph.	gr. j
Cocainæ hydrochloratis	grs. iij
Menthol	grs. vj
Pulv. acidi borici	ʒ ij
Bismuthi subnitratis	ʒ ij
Pulv. benzoini	ʒ iij

M. Sig.: Snuff a pinch up the nostrils several times daily.

Alumnol in Dermatology.

Dr. J. Abbott Cantrell (*College and Clinical Record*) says: "Alumnol has proven itself of decided advantage in my service at the Philadelphia Polyclinic, where I have advised its use in a hundred cases. It was found serviceable in acute vesicular eczema, erythema intertrigo, chronic eczema, non-syphilitic ulcers, ringworm and impetigo contagiosa. It was used in the form of powder, 1 part to 3 parts of starch, and as an ointment in strength varying from 20 grains to 2 drams to the ounce, and as a solution in the proportion of 2 drams to the ounce of water."

KEELEY CURES.

In *The Christian Advocate* of July 26, 1894, ministers and physicians among our readers were asked to assist us in obtaining accurate and impartial statistics of the results of the so-called Keeley cure of drunkards. The public has often been assured that ninety-five per cent. of the persons treated in the Keeley cures are cured or reformed, and that relapses are few. We stated that of those we had met four have relapsed, two committed suicide, and several others were in asylums; the sum total of these being more than fifty per cent. of the small number that we chanced to know. But as that might be true, and the statements made by the agents and managers of Keeley cures, who deal with a large number, might also be true, we deemed the subject of sufficient importance to collect statistics upon it.

The number of persons who have been inmates of the various Keeley institutions is large and scattered through all sections. So far as we can ascertain, at least seven thousand ministers and fifteen hnndred physicians, distributed over the United States and in foreign countries, are among our subscribers.

Our plan was this: We addressed three questions exclusively to ministers and physicians:

1. How many do you know who have taken the Keeley treatment?

2. Of those who have taken it, how many, to the best of your knowledge and belief, have remained sober and totally abstinent for a period of nine months or more?

3. How many have relapsed in less than that time, or have committed suicide, or become insane, or have been physically seriously injured by the treatment?

The explanation accompanying these questions were as follows:

Except in the case of personal acquaintances, we do not ask for information from subscribers in general because we would have no way of preventing the duplication of returns. By confining it to ministers and physicians we get one or two persons in a locality, and can correspond with them as to whether they have duplicated.

We wish no information from agents or managers of "Keeley cures" or graduates thereof. The former are excepted because of their business interests; the latter, because in that case we should get repeated information from the same locality. Neither do we wish mere hearsay information from ministers or physicians. If A tells B that he knows C; that C was a drunkard and was cured by a Keeley institute, and has never touched a drop of liquor since, and B tells us about it, it is of no value in this case. Nor do we wish names, but on the honor of a minister or physician we merely wish, as stated above, the number that he knows to have taken the Keeley cure, and what were the results. Nor do we wish this inquiry to be confused with any other "cure." Since Dr. Keeley began to be noted and to make vast profits, scores of imitators have sprung up, as is always the case; and he has a number of times declared that his institutes have been traduced by the fact that other graduates, who have lapsed, have been charged to them.

We will tabulate and publish the returns.

No sooner had this proposition been made than the Keeley Company sent us a long document denouncing our method, and containing severe attacks upon physicians, and indirectly upon ministers, as prejudiced persons whose testimony could not be relied on. This they say we may publish if we see fit, which we may do when we present the results. It will at least afford to the reader an opportunity of judging whether our exclusion of the company as a source of information was wise or unwise.

Various Keeley Leagues and Auxillary Associations passed resolutions accusing us of being prejudiced and declaring that our method of securing information is not adapted to elicit truthful returns. In various parts of the country circulars were sent to our ministers, urging them to be very particular to send the whole number of graduates that they knew, and other circulars especially stirring people up to send information favorable to the cure.

We suppose that ministers have no prejudice one way or the other unless employed by the company; that as a class, if they answer our appeal for information at all, they will tell the truth. And we be-

lieve that physicians, unless interested in some other system of treating such cases, will tell the truth. Further, we think ministers would be quite likely to come in contact sooner or later with a large number of permanent cures; for nothing is more talked about in a community than a genuine reformation from publicly known drunkenness. And we suppose that physicians would be most likely to come in contact with relapses, especially when followed by insanity, suicide and other conditions requiring care of treatment.

Some unsophisticated persons connected with Keeley institutions—before they heard the proclamation of hostility from headquarters—wrote us commending in high degree the simplicity of the plan.

It must be remembered that there are alleged to be hundreds of thousands of persons who have taken these treatments in every State in the Union.

Now we have not examined the results of our inquiries. Immediately after publishing the proposition, large numbers of letters began to arrive. We instructed the office editor to file them carefully.

The investigation, so far as we are concerned, will be terminated on the last day of March. At that time the tabulation of the returns, which will be made by disinterested persons, will be submitted to the editor. The result will then be announced.—*Christian Advocate* (N. Y.), Jan. 31, 1895.

THE ANTISEPTIC TREATMENT OF SCARLET FEVER.

Dr. W. Jamison (London *Practitioner*) says that there appears to be four points requiring consideration: (1) The course of the infectious principle, (2) the treatment of the throat and mucous membranes, (3) the management of the skin, (4) the value of the "so-called" complete isolation alone, as compared with antiseptic measures and restricted isolation.

1. There are three routes by which scarlatinal poison can enter the system: (*a*) by direct inoculation, which is rare; (*b*) by being swallowed, a more common source, the medium frequently being milk, a fluid in which the virus grows rapidly; (*c*) by inhalation, the most common method of transmission, Probably in all cases the first symptoms are manifested in the throat; the second, usually within twenty-four hours, as the eruption on the skin. It is almost certain that during the period of pyrexia the virus is multiplying in the blood, and is in process of being conveyed to the under surface of the skin. Deposited beneath the epidermis, it rises through its layers and is finally cast off in flakes of exfoliating cuticle. Dr. J. has seen desquamation commence on the fourth day, but in the majority of instances it manifests itself from the ninth to the eleventh day. The process of "peeling" is not completed, if uninterfered with, until the end of the eighth week. It is never absent in a genuine case of scarlet fever.

2. The best application to the throat is a spray of peroxide of hydrogen, ten-volume strength, repeated from three times daily to once in two hours. It should be continued, the intervals being extended, till its application no longer induces pain.

3. As regards the management of the skin, in the stage of exanthem we must favor the development of the rash by warm baths, which are best given at night, after which the entire surface must be smeared with eight ounces of almond or olive oil, containing a fluid dram of carbolic acid and two or four fluid drams of oil eucalyptus. When desquamation commences the warm baths must be supplemented by soap. Keep the patient in bed for three weeks, who should not be allowed to mix with others until peeling is completed and the hair washed several times.

4. Dr. J. is of the opinion that isolation alone cannot prevent infection, but no risk exists if the antiseptic precautions described are attended to. The nurse ought to wear a cotton wrapper, which can be laid aside when she leaves the room. The bed and body linen should be immersed in carbolic solution after being taken from the room.—*The Medical Progress.*

THE ADVANTAGE OF ATMOSPHERIC DISTENTION OF THE RECTUM, WITH DISLODGEMENT OF THE SMALL INTESTINES, IN THE BIMANUAL EXAMINATION OF UTERUS, OVARIES AND TUBES.

Howard A. Kelly (*American Journal of Obstetrics*), suggests a procedure for overcoming the embarrassment experienced by the crowding of the small intestines down into the pelvis and the consequent liability of making a false diagnosis of pelvic disease. Coils of small intestines in the pelvis containing fluid often feel tense and fluctuating, and thus readily impose themselves upon the examiner as large cystic ovaries, or leave him in doubt as to their true nature. The complete removal of these impediments may be satisfactorily effected in the following manner: The patient is placed in the knee-breast posture, with shoulders on the table and hips high and thighs vertical. The anal orifice is opened by a small speculum or tube, allowing the air to rush into the rectum, The explanation of this phenomenon is that, upon assuming the knee-breast posture, the small intestines gravitate along the anterior abdominal wall into the upper abdomen towards the diaphragm, creating a suction at the most elevated portion, which is the pelvic extremity, by means of which the whole ampulla and rectum balloon out with air as soon as the anus is opened, and the distended rectum applies itself broadly over the posterior surfice of the uterus and left broad ligament. Before making such an examination, both rectum and bladder must be thoroughly emptied. Immediately after filling the rectum with air the tube is removed, the patient placed in the ordinary dorsal position with limbs flexed upon the abdomen, and the bimanual examination made per rectum and abdomen. The index finger introduced within the anus experience at once the sensation of entering a large cavity filled with air, in which the customary resistance is absent. The communication with the upper bowel between the utero-sacral folds is, under these circumstances, readily found, and the finger is conducted behind the broad ligament, when, on using the outside hand in assistance, uterus, broad ligaments, ovaries and tubes are at once palpated directly through the rectal wall, without resistance and with startling distinctness. The true pelvic viscera thus seen, as it were, to be skeletonized in the pelvis, lying so clearly exposed to touch that the minuter surface peculiarities, fissures and elevations, and changes in consistence, can be detected, and a diagnosis made more satisfactorily, more rapidly and with far less effort than under ordinary conditions.

TEA INTOXICATION.

To speak of this beverage as "The cups which cheer but not inebriate," must be regarded as an instance of purely poetic license.

As the best work of the poet is likely to be produced when he is thoroughly intoxicated with his subject, this line may be regarded as of such origin. Certainly it belongs to the realm of poetic fancy rather than to that of scientific fact. And it may be claimed that its author, by his subsequent melancholia and suicide, demonstrated the danger of indulgence in this direction.

No one who has practiced among the poor of a large city can have failed to recognize the baneful effects of excessive tea-drinking, especially among sewing women. James Wood (*Medical News*) says:

Of 1,000 consecutive cases applying for general treatment at our largest dispensary, 100, or 10 per cent. were found to be liberal indulgers in tea, and suffering from its deleterious effects, and no one of which came for treatment of the tea habit, but for various other complaints. They were loth, when apprised of the cause of their

illness, to believe that such a harmless household commodity ever produced any bad effects. Of these 100 cases, 20 per cent. complained of persistent dizziness, 19 per cent. of indigestion, 45 per cent. of headache, 20 per cent. of despondency, 19 per cent. of palpitation of the heart, and 15 per cent. of insomnia.

When tea has been used for a considerable period in excess and its detrimental action has been constant, we have well-defined symptoms supervene, a few of which are such as vertigo, mental confusion, sensible palpitation of the heart, restlessness, insomnia, hallucinations, "nightmare," nausea, neuralgia, anorexia, constipation, prostration and anxiety, and a peculiar kind of intoxication ending after hours of vigil in a torpor from exhaustion.

What worse line of symptoms could follow the use of a beverage so commonly employed, it is hard to imagine, and that many people use it to excess is unquestionable. Many have confessed to an inability to "get through the day" without copious imbibitions of what is, in many cases, a strong decoction. Some drink every twenty-four hours as much as fifteen pints, and some there are who are unable to judge of how much they consume.—*Philadelphia Polyclinic.*

THE PRESENT POSITION OF THE LICHEN QUESTION.

This was one of the subjects submitted to the Dermatological Section of the International Congress in Rome, and the opinions expressed thereon by two of the speakers have come under our notice. Mr. Malcolm Morris, after an exhaustive review of the several statements made by authors of eminence since Willan's time, showing the confusion which even now reigns as to what is and what is not to be regarded as lichen, thus formulates his own conclusions as a contribution to the settlement of the question. (1) Lichen is not a disease, but a type of lesion. (2) The term should be reserved for the clinical entity described by Erasmus Wilson under the name of lichen planus, which is the same as Hebra's lichen ruber. (3) The affection described by Kaposi under the name of lichen ruber acuminatus is identical with that described by Devergie and Besnier as pityriasis rubra pilaris. (4) Other forms of lichen—obtusus, hypertrophicus, verrucocus, etc.—are variants of the typical form, the Hebra-Wilson typical lichen planus. (5) The group of symptoms to which the name of lichen planus is applied is probably caused by a variety of factors, but at present we are almost entirely in the dark as to its pathogenesis. (*Med. Press and Circular*, June 27, 1894.) Neisser, again, while he agrees with much of what has been said by Malcolm Morris, holds that, (1) Lichen ruber appears in two principal forms, which are to be distinguished as lichen ruber dianus (Wilson) and lichen ruber acuminatus. All other eruptive forms described under different names are modifications of this chief type. (2) Pityriasis ruber (Devergie Besnier) is a disease *sui generis* and a keratinosis, that is. a disease with essential anomalies of keratinization of an acquired character. At the same time he does not strictly adhere to the description of lichen ruber acuminatus given by Hebra, senior, nor to that provided by Kaposi, since he thinks that the two authors last named referred to entirely distinct diseases, the sole common element being the acuminate form of the lesions. It would thus appear that for some time to come many various opinions will continue to be held as to the constitution of the lichen family.

Sterilization of Doctors.

It has been proposed by Gutmann that stations be erected in convenient localities in cities and large towns where physicians may go to be thoroughly disinfected immediately after they have visited a case of infectious disease, and before paying any further visits. The operation will take about fifteen minutes, and then the doctor may go about his business, proud in the consciousness of being clean and no longer a menace to the health of his fellows.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Intubation in Germany.

The Children's Hospital at Leipsic is the only one in Germany where intubation is regularly employed. Baginski formerly used it, but now prefers tracheotomy in most cases. The results at Leipsic are very good, over 200 intubations having been made in the last two years with 32 per cent. recoveries. Carstens has modified the O'Dwyer tube a little and inserts it while the child is lying on its back in bed instead of sitting in the upright posture. The presence of a tube in the larynx usually renders the swallowing of liquids difficult, and thus the taking of the necessary amount of food is apt to be interfered with. This difficulty is met in America by the giving of solid foods, or by placing a patient upon the back with the head lower than the rest of the body while swallowing. In Leipsic, however, all intubated patients are fed through the catheter, so that there is no diminution in the amount of food given. The tube is worn from two to five days. If left longer than this, it is apt to cause ulceration. If at the end of five days relief of stenosis is called for, tracheotomy is performed. This has been necessary but twelve times in two years.—*Physician and Surgeon.*

The Heart in Typhoid Fever.

Dr. Huchard considers that the cardiac symptoms in typhoid fever may be due not only to myocarditis, but also to functional disturbances of the innovation of the heart. These symptoms disappear far too rapidly to be ascribed to myocarditis. Clinical experience has also shown that bradycardia, tachycardia and all other deviations from the normal rhythm of the heart depend upon a functional disturbance of the pneumogastric nerves. The action of the microbial toxins may also be purely functional.—*Med. Week.*

Pathogenesis and Treatment of Influenza.

It is well known how popular the quinine treatment of influenza was when that *maladie a la mode* visited our shores. So far as my knowledge goes this mode of treatment was strictly empirical, no laboratory experiments having been made on its action. The medical world will therefore be glad to know that the experiments of M. Mosse have confirmed the good opinion entertained of the value of this drug in combatting la grippe. Rabbits were inoculated with the blood of influenza patients, and then quinine was injected subcutaneously. 4 out of 6 of these animals remained unaffected, while test rabbits unprotected by the drug became very ill. Again, rabbits inoculated with pure cultures of Pfeiffer's microbe (furnished by M. Roux) were quite capable of supporting this inoculation, provided subcutaneous injections of quinine had been previously practiced. Of 3 unprotected rabbits, 2 were killed by the inoculation. Efforts to cultivate (on gelatine) the pathogenic bacillus from the blood of an influenza patient were always unsuccessful. In one instance the pneumococcus and in another the staphylococcus were obtained. The blood of animals experimentally infected with influenza yielded the specific microorganism only on one occasion. This culture was endowed with but feeble vitality and proved to be non virulent. M. Mosse arrives at the conclusion that the influenza bacillus is found only exceptionally in the blood, and that when so found its virulence is enfeebled. It is, moreover, unable to live in an organism in which the drug in question circulates, viz., quinine. It would thus appear that the exhibition of quinine as a prophylactic is justified; that it should be prescribed in large doses as an abortive agent; and that, finally, grave secondary infections, especially if due to the pneumococcus, call for hypodermic injections of quinine.—*Lancet; Med. Rec.*

Some Symptoms Which Simulate Disease of the Pelvic Organs in Women—Their Causes and Treatment.

Dr. A. Rabagliati: The condition often described as ovarian neuralgia is, as a rule, neither ovarian nor neuralgic, though both may coexist; but is essentially a rheumatic perimysitis, due to improper nutrition and the absence of proper exercises in the open air, and can be cured without operation. In the kind of cases under consideration it is assumed that there is no gross disease of the pelvic organs beyond, perhaps, a slight displacement of the uterus or its appendages. In such cases oophorectomy is, in my opinion, an unjustifiable operation, and a much better procedure is my own operation of cutting down on the umbilicus, rawing the surfaces and bringing them together, though, as a rule, not even this is necessary. In the examination of these women we find tenderness of the oblique muscles of the abdomen, of the recti muscles, of the umbilicus itself, of the quadratus lumborum muscles, of the sacroiliac synchondrosis, and also of the sacral origin of the glutei maximi. This tenderness, I think, explains the complaint usually made by these women of being constantly tired. The kind of pain is an aching one, such as is associated with trouble in muscles, rather than numbness, tingling or smarting, such as characterize nervous involvement. Other muscles may also be affected, such as the solæi and gastrocnemei, the quadriceps ex-

tensors, etc. Minor degrees of disease of the uterine appendages may of course coincide with this condition, but the latter is really the main cause of the patient's suffering. There are many reasons for believing that this muscle trouble is rheumatic in character, and these have led me to designate the affection as perimysitis rheumatica. The principal cause is, I believe, the improper feeding of these women, especially the bread and tea which they take in such large quantities, and the best treatment is to place them on a liberal diet, combating the rheumatism by appropriate remedies and washing out the waste with hot water taken an hour after food three times a day. I wish to lay great stress also on the value of bathing followed by methodical exercises calculated to put into action the disused muscles.—*Arch. Gynec.*

Dangers of Naphthol.

Baatz, in the British *Medical Journal*, has seen acute nephritis follow friction with an ointment containing 2 per cent. of naphthol beta in two brothers aged six and eight, respectively. The remedy was applied for scabies. This was cured, but three weeks afterwards albuminuria with edema of the lower limbs came on. One of the boys died, and the diagnosis of nephritis was verified by post mortem examination. In neither case had minuria previously existed, nor was there any history of an affection which could have been the starting point of nephritis. The author therefore warns against the use of naphthol beta as a remedy for scabies in spite of the powerful curative effects.

Spontaneous Cure in Amebic Dysentery.

The rarity of spontaneous cure in such severe forms of dysentery has led Drs. George J. Preston and John Ruhrah to report a case in the New York *Medical Journal*. A colored man aged twenty-two, with a fairly good history, was admitted on account of dysentery. Examination of the stools showed the typical amebæ. Patient was given large doses of the tincture of iron. The dysentery was not treated, but in the next few days the amebæ disappeared and the man recovered.

Puerperal Neuritis.

With an expansion of our knowledge of the complications of the parturient and puerperal states, and with a glowing familiarity with the lesions of the peripheral nerves, we have come to learn that the intoxications dependent upon infection through wounds and lacerations resulting in the course of childbirth may give rise to a multiple neuritis comparable to that of rheumatic, plumbic, alcoholic, or other like origin. A typical case of this kind was recently reported by Lountz (*Nouvelles Archives d'Obstetrique et de Gynecologie,*) at a meeting of the Societe de Neurologie, of Moscow. The patient was a primipara, twenty-four years old, who passed through pregnancy and labor without complication, the child dying, however, on the fifteenth day. Three weeks after the labor the woman presented swelling of the face, œdema of the extremities, difficulty of deglution, diplopia, pains in the extremities, and then numbness and weakness of the upper and lower members. Common sensibility was little affected, but the muscular sense was impaired. The knee-jerks and the elbow-jerks were abolished, and electric irritability was diminished. These symptoms were progressive for two weeks. To them were added arrhythmia of the heart, acceleration of the pulse, and attacks of suffocation. The lower extremities became entirely paralyzed. By and by, however, the symptoms gradually ameliorated, except the paraplegia which persisted for a long time. It is assumed that this depended upon a polyneuritis due to infection through a laceration of the perinæum incurred during labor.—*Medical News.*

Physiological Rest in the Treatment of Prolapse of the Rectum

Bryant, (*Mathew's Medical Quarterly*), reports the case of a man operated on seven times for the relief of extensive prolapse of the anus, with its attendant distressing symptoms. Until the last operation, surgical intervention had been of little benefit. Bryant, to whom he finally came, made an artificial anus in the left groin, putting the patient to bed for two weeks, meaning to proceed to further treatment. But this operation was followed by so much relief and by such a marked diminution in the pressure that he was content to adopt no further procedure. He submits the following proposition as a conclusion to his paper:

That the proper performance of the physiological functions of the rectum contributes greatly to the advancement of rectal disease and to the afflicted.

That the complete vicarious discharge of the fæces through an artificial anus located in the sigmoid flexure reduces the physiological demands on each structure of the rectum to a minimum.

That the lessening of the physiological requirements is commonly in direct proportion to the diminution of the fæcal flow through the rectum.

That the cessation or lessening of the fæcal discharge per rectum exercises a palliative and curative influence on diseases of the rectum.

That in certain cases of obstinate rectal prolapse the formation of a vicarious channel for fæcal discharge is justifiable, both as a palliative and curative measure.

That the preliminary establishment of such a channel for the purposes of cleanliness and the prevention of infection is justifiable in many grave operations for prolapse of the rectum.

That the dangers attendant on the formation of an inguinal anus are much less than those invited by the contact of fæcal discharges with large operative surfaces of the rectum.

That the case just presented has been, without special risk, greatly benefited, and

may be finally cured, through the agency of an artificial anus.

That when cure takes place, great care must be excercised thereafter, otherwise the prolapse will return.

Bichromate of Potassium as a Remedy in Gastric Affections.

We offer the following synopsis of a paper on the above subject, which was read at the International Medical Congress by Professor T. R. Frazier: Notwithstanding the assertion made in 1883, by so high authority as Vulpian, of the value of bichromate of potassium in the treatment of several forms of gastric disturbance, this substance has not yet gained a position among the many substances that are used in the treatment of these affections. Having, in 1884, treated with gratifying success a case of persistent gastric disorder by the administration of small doses of bichromate of potassium, I have since that time administered it in a large number of cases, and the results have been so favorable that I feel myself justified in now stating my opinion of the therapeutic value of the substance. The cases have been recorded in two groups, the first group comprehending 18 cases of various forms of dyspepsia unassociated with evidence of gastric ulcer, and the second group, 10 cases in which distinctive symptoms of ulcer had been present at some previous time. The doses administered in the above cases have varied ½ grain to 1-6 grain, twice daily, and in most instances the smaller dose was found to be sufficient. The dose should be given during fasting and on as empty a stomach as possible. The administration was effected in the form of pills or an aqueous solution which may be flavored with tolu or orange. An examination of these cases shows that bichromate of potassium is capable of relieving, and often in a short time of removing, the entire group of symptoms—if we except constipation and anemia—encountered in dyspepsia, and especially pain, nausea, vomiting and gastric tenderness. In a few cases of acute gastrice ulceration, with hematemesis, in which I have given bichromate of potassium, the results were not favorable, as it did not succeed in checking the bleeding. Bichromate of potassium possesses a strong anti-putrefactive power, which is exhibited in albuminous, saccharine and phosphatic urines, even with a 0.01 solution. This action probably constitutes one of the causes of its anti-dyspeptic therapeutical value, but there are undoubtedly other causes, such as direct or indirect analgesic action, and probably a selective action on the nutrition of function certain histological structures, which I am now engaged in endeavoring to determine.—*Lancet.*

Causes of Sexual Debility.

Dr. F. R. Sturgis gives the following summary of his views at the termination of a very instructive paper: 1. That the cases of sexual debility which are marked by imperfect erections and by premature emissions are usually, if not entirely, due to hyperæsthesia of some portion of the urethra. 2. That masturbation has very little, if anything, to do with it beyond the fact that if indulged in to excess it may induce a tendency toward this hyperæsthetic condition, but this is no more marked in masturbators than it is in those persons who indulge to excess in the venereal act. 3. That organic stricture has little, if anything, to do with it; but that associated with this hyperæsthetic condition there is an irritable condition of the canal which produces spasmodic contractions of the urethra upon attempts to pass instruments, oftentimes during the first act of micturition and at the time of connection. 4. That varicocele plays no unimportant part in these cases. 5. That neuralgia of the testis, if a cause of this disease, induces it merely as a secondary consequence to the pain, which is one of the distinguishing features of this disease. 6. That tuberculosis, syphilis and gonorrhœa may also play their part, and should all be reckoned with in summing up the causes which may induce this peculiar and depressing condition of affairs.—*Gaillard's Med. Jour.*

Chronic Recurrent Tetanus Treated with Thyroid Extract.

At a recent meeting of Berlin Medical Society, Gottstein reported a case from the clinic of Mikulicz, in which a thirty-four-year-old man who had suffered from attacks of tetanus since his twelfth year, was found to have no signs of a thyroid gland; and as tetanus is one of the symptoms observed in animals deprived of their thyroids, he was treated by having a goitre from another patient implanted in the abdomen. The result was very gratifying as the frequency of the attacks was very much reduced. This improvement was only temporary, whereupon a second similar implantation was made, with the same result, decided improvement with subsequent relapse into the original condition. The man was then put upon thyroid extract by the mouth, whereupon the attacks diminished gradually from twenty a day to three or four a day, at which number they have remained. The general condition has been much improved.—*Deutsche Med. Wochenschrift.*

Turpentine in Incontinence of Urine.

The unpleasant smell emitted by persons suffering from incontinence of urine can be conveniently covered, according to Dr. Emminghaus by means of ten-drop doses of turpentine administered in milk or water three times a day. This converts the smell of stale urine into an odor resembling that of violets, as is well known to persons who have taken turpentine. The remedy is perfectly harmless in most cases, and has been given by Professor Emminghaus for many weeks at a time without any inconvenience. It is, however, contraindicated in ulcer of the stomach, gastric catarrh, and nephritis, and also in

some persons in whom turpentine tends to upset the digestive functions.— *London Lancet.*

Lactophenin.

If the results of Jaxuet and of Strauss (*Abst. in Fortschritte d. Medicine,*) should be confirmed, lactophenin will certainly fill a long-felt want for an effective antipyretic which does not at times cause alarming symptoms. The compound is a near relative of phenacetin, differing from it only on having the acetic acid which is combined with the ammonia of the latter, replaced by lactic acid. It is said to be a prompt and effective antipyretic with the addition of a decided hypnotic effect. Its great advantage, however, is in the freedom from disturbing secondary effects. Even where the fall of temperature produced by it has been very great (9°F.), the patient feels perfectly comfortable with a quiet, full pulse and a clear intellect. As an anti-neuralgic and sedative it ranks with antipyrine, phenacetin, etc.

To Relieve the Thirst of Diabetics.

Pilocarpin may be administered in solution or in pill form. The pills are best prepared by the addition of glycerin and gum arabic. Each contains gr. $\frac{1}{60}$ of pilocarpin nitrate. For the solution the following form is given:

Pilocarpin nitrat	gr. ½
Spirit vini dilut	mxx
Aquæ	ʒj

M. Sig.: The tongue is to be moistened with 5 or 6 drops of this solution four or five times daily.

—*Nouv. Remedes.*

Vomiting in Pregnancy.

Lutaud (*Rev. Obstet. et Gyn.*) states that vomiting of pregnancy is best treated by cocaine. The action of this drug is often strengthened by combining it with antipyrin. Thus the following prescription:

Chlorhyd., cocaine	grs. jss
Antipyrin	grs. xvi
Aq. dest	ʒ iv

Sig.: Teaspoonful every half-hour until the vomiting ceases.

If the stomach will not tolerate the quantity of liquid, ten drops of a one and a-half or two per cent. solution of cocaine are administered, repeated at one or two-hour intervals.

At times the application of cocaine to the os is extremely valuable. The following prescription may be used:

Hydrochlor. cocaine	grs. xvi
Ext. bellad	grs. iv
Vaseline	ʒ ss

Cotin's method of dilating the os with the finger sometimes causes immediate cessation of vomiting. Occasional success will follow Routh's procedure, which consists in exposing the uterine neck by means of a speculum and painting with tincture of iodide. In cases of moderate severity the following mixture will be found serviceable:

Tinct. iodine Chloroform	āā ʒ ij

Sig.: Five drops night and morning at meal times, taken in Seltzer-water.

—*Kan. Med. Record.*

Hydrochlorate of Chalk for Pruritus Ani.

Take (*Sem. Med.*), a piece of cotton gauze two or three centimeters long, which has been moistened with a solution of hydrochlorate of chalk, two to the hundred. Push up the anus and leave in place until sharp smarting commences. Then remove it and wipe surface of anus dry. Itching immediately ceases. If it should return employ the same proceeding. It appears that this solution simultaneously clears up all the eczematous patches about the anus and scrotum, a condition so generally concomitant with an anal itch.

Chrysarobin in Chronic Ringworm of the Scalp.

Duhring (*American Journal of the Medical Sciences*), as the result of an extended experience with a large number of chronic cases of ringworm of the scalp in a boys' school, arrives at the conclusion that chrysarobin was the most active and potent parasiticide employed. It was used in various strengths, but generally in the form of an ointment of one dram to the ounce. While, as a rule, it was well tolerated, the writer advises care in its employment, especially in avoiding the face.—*Int. Med. Magazine.*

A New Method of Making Palatable and Digestible Milk.

Dr. Robert T. Edes, of Boston, gives a valuable way of preparing milk where other methods have not proved useful:

A pint of milk is gently warmed. Into it is dropped, very slowly and with constant stirring, about twenty minims of the dilute hydrochloric acid of the United States Pharmacopœia. The milk should be stirred until it cools. In this way a very fine flocculent coagulum is produced, floating in the whey, which is easily accessible to the digestive secretions, while the whole fluid has lost somewhat of the flat and cloying taste which makes it unacceptable to so many. It will be noticed that milk prepared in this way differs from the various "wheys" in the highly important particular that the casein is retained and used, instead of being separated out as a distinct product, while it avoids the bitterness of pancreatinized milk.—*Boston Med. and Surg. Jour.*

Potassium Nitrate in the Treatment of Phlegmasia Alba Dolens.

Hovnanian, (*Medical News*) describes his use of nitrate of potassium in this affection:

It has fallen to his lot to treat three well-marked cases of phlegmasia alba dolens with potassium nitrate with such gratifying results as to seem to justify publication.

Mrs. H., twenty-three years old, was delivered of her first child by her family physician with instruments, and sustained extensive lacerations of the cervix uteri and perineum, which at the time were not repaired, but were left for a secondary operation. Twelve days after delivery she complained of pain and heaviness in the left leg, and within three days there developed well-marked phlegmasia. On the fourth day of this complication the writer saw the patient in great agony, with a temperature of 105.2° F., a pulse of 130, and respirations 25. The limb was so turgid and swollen that there seemed to be great danger of gangrene or rupture. The woman was at once given morphine sulphate (⅛ grain) hypodermically, and her limb was wrapped with cotton and placed on a feather pillow at a very obtuse angle. Hovnanian then prescribed a solution of potassium nitrate in water, respresenting 5-grain doses, to be given every hour until his return. Seven hours later he found his patient in better condition, with a temperature of 103° F., a pulse of 112, and respirations 22, and with less pain and discomfort. The swelling seemed to be less tense and the veins less engorged. The nitrate was continued as before until morning, when he found her in yet better condition. She had slept well during the night, although she had been wakened regularly for her medicine. Her temperature was 100° F., her pulse 95, her respirations 20. The swelling was reduced to less than half, and the returning circulation was fairly well established. There was no pain whatever and but slight tenderness on pressure. The medicine continued every two hours during the day, until the author saw her late in the evening, with a temperature of 99° F., a pulse of 90, and respirations 18. The swelling had almost entirely gone and everything was in good condition. The nitrate was continued for two days in smaller doses and at longer intervals, and then discontinued.

Two other equally typical cases are also recorded in this paper.

Nephritis Following Friction with Naphthol.

In the *Revue internationale de medicine et de chirurgie pratiques* there is an abstract of an article on this subject by M. Baatz which appeared in the the *Centralblatt fur innere Medicin*. The author relates two cases of nephritis following naphthol frictions for the itch. In the first case, that of a boy nine years old, the nephritis, which was not very pronounced, manifested itself in edema of the legs, the feet, and the scrotum, accompanied with slight albuminuria. Recovery followed very quickly under the influence of a proper diet and baths. In the second case, that of a boy six years old, anasarca and symptoms of broncho-pneumonia were observed when he entered the hospital. The urine, which was brownish in color, contained albumen, hyaline casts, and red blood corpuscles. Notwithstanding the treatment, which was carefully applied as soon as the symptoms appeared, the situation became aggravated and the child died four days after his entrance into the hospital. At the autopsy extensive broncho-pneumonia of the left base and parenchymatous nephritis were found. The author thinks that in both cases nephritis had been provoked by the naphthol frictions. He recalls the fact that similar cases have been observed before by other authors. Kaposi has published an account of a boy who, after friction with naphthol for prurigo, was taken with ischuria, with bloody urine, vomiting, loss of consciousness, and eclampsia which persisted for several days. The child recovered. Lewier has related the case of a man who, after fifteen days of naphthol frictions, was taken with acute nephritis with albuminuria. Finally Frohmuller has observed three cases of naphthol poisoning where the principal symptoms were acute nephritis and attacks of mania.

The Dietetic Treatment of Phthisis.

The following suggestions by Dr. Henry P. Loomis (*The Practitioner*) are worthy of careful consideration:

1. Never take cough mixtures if they can possibly be avoided.
2. Food should be taken at least six times in the twenty-four hour; light repasts between the meals and on retiring.
3. Never eat when suffering from bodily or mental fatigue or nervous excitement.
4. Take a nap or at least lie down for twenty minutes before the midday and evening meal.
5. Take only a small amount of fluid with the meals
6. The starches and sugars should be avoided; also indigestible articles of diet.
7. As far as possible each meal should consist of articles requiring about the same time to digest.
8. Only eat so much as can be easily digested in the time allowed.
9. As long as possible systematic exercise should be taken to favor assimilation and exertion; when this is impossible, massage or passive exercise should be undergone.
10. The food must be nicely prepared and daintily served—made inviting in every way.

Chronic Constipation and Its Treatment.

The causes of constipation (James D. Staple in *Med. Times and Hosp. Gaz.*) are:

1. Lack of tone in the muscular coat of the intestines causing a decrease in peristalsis, usually due to imperfect regional innervation.
2. Deficient secretion or excessive absorption.

People leading sedentary lives are predisposed to constipation.

The symptoms (excepting in those cases due to organic disease) are:

Loss of appetite, imperfect digestion, nausea, headache, irritability, mental depression, bad complexion, acne, sleeplessness. Hysteria in the female and hypochondria in

the male have been often caused by constipation, and it is even stated that a condition of disease bordering upon insanity may be brought about by a long-continued defective formation of fæces and imperfect action of the bowels.

Moreover, the material which should have been removed will accumulate in the blood, and in consequence such diseases as gout rheumatism, etc., may be developed.

The treatment may be divided into (1) non-medicinal and (2) medicinal. Under the non medicinal we may include: (*a*) correction of diet; (*b*) fluids before breakfast; (*c*) exercise; (*d*) cold bath or rubbing the body with a rough towel; (*e*) kneading the abdomen; (*f*) going to stool at a regular set time.

In the medicinal treatment of chronic constipation avoid giving purgatives, the reason being that patients acquire the habit of depending on them. Small glycerin suppositories are highly recommended, being rapid and certain in action and their use unattended with griping or irritation of the gastro-intestinal tract. In cases where aperients must be given cascara sagrada is recommended, but even in these cases it is well to begin with some natural mineral water.

Eucalyptol in Eruptive Diseases.

The following, says an exchange, will increase the activity of the skin and besides prove an excellent antiseptic:

Eucalyptol	ʒ ss
Carbolic acid	grs. v
Lanoline	ʒ ij

M. Apply over eruptive surface.

The Significance and Etiology of the Premature Discharge of Meconium.

E. Rossa (*Archiv. f. Gynak.*) states that it is commonly believed that the escape of meconium before term is a sure sign that the fœtus is in danger of asphyxia, and is therefore an indication for the hastening of delivery. The author's personal investigations have led him to doubt the correctness of this teaching. In a large number of cases the escape of meconium has no significance of the kind generally attached to it. The cause of the phenomenon is simply increased intestinal peristalsis, which may indeed be due to asphyxia, but may also be due to other less well defined causes. Among these the principal are diseases of the mother, and particularly gastro-intestinal disorders.

Chronic Rhinitis and Pharyngitis.

Dr. H. M. Dunlop, sanitarian at Battle Creek, Mich., claims (says *Prescription*) to have obtained excellent results from the application of the following:

Ol. cinnamon	gtts. xx
Eucalyptol	ʒ iij
Ol. gaultheriæ	gtts xxx
Menthol crystal	grs xx
Liq. albolene	ʒ iij

M. Use with atomizer.

Virchow's View of the New Treatment of Diphtheria.

Virchow's opinion of the efficacy of the new treatment by blood serum of diphtheria may be thus summarized: The serum exercises a strong protective effect for weeks, perhaps even for three to four months; but it remains to be seen whether this effect is permanent, and whether—and this is the cardinal question—it is really possible to cure diphtheria by this remedy. Much however, is gained if we succeed in protecting even one child in a family in which three or four are ill of this malady. And that we may accomplish this appears extremely probably. —*German Correspondent, Med. Press.*

Chloral in the Treatment of Boils.

(Le Chloral contre les Furoncles. *Bull. Gen. de Therapeutique.*) By M. Spehn.

The author recommends very highly as far superior to all other treatment the use of chloral externally in this troublesome class of affections. He directs that the boil be kept covered with a tampon of cotton-wool soaked in the following solution:

Chloral. hydrat.	ʒ iiss
Aquæ. Glycerin.	ää f ʒ v.—M.

—*Int. Med. Magazine.*

SURGERY.

Circumcision.

In most cases the foreskin adjusts itself to conditions of perfect cleanliness at the time of puberty, if not before. Physicians are not so senseless as to unnecessary mutilate themselves and their families. Circumcision is a relic of barbarous and semicivilized times, before soap and water and sanitation had been preached. It no doubt served a useful purpose among the nomadic tribes of tropical countries. But in these days physicians should cease to preach or impose upon their patients an unnecessary and irrational mutilation.

The rite which in these modern times might be substituted for the early religious ceremony of circumcision would, according to some, be resection of the spermatic cord of the vicious and defective classes, so that they should cease to propagate their kind. Spermatorectomy will probably triumph over and replace circumcision if anything does.—*Editorial in Med. Rec., N. Y.*

Chordee.

In a paper on "Local Anæsthesia," Dr. Wm. P. Carr, of Washington, D. C., writes, *Med. Buelletin:* "In this connection I may mention a fact well worth knowing, and I think not generally known, the chordee may be entirely and promptly relieved by putting on a condom containing two or three drachms of a two per cent. solution of carbolic acid, and that any pain in the penile portion of the urethra or pendulous penis may be controlled in this way."

Strangulation of the Tonsils.

Dr. Marcel, who is chief of the clinic for diseases of the nose and throat at Bucharest, describes the removal of the tonsils with the cold snare, which he has performed in fifty cases. He always makes use of a snare with three rings and without a screw, employing the same kind of wire as that used for removal of nasal polypi. In the after treatment he recommends gargles of carbolized water, with addition of oil of peppermint. On the following day in place of the tonsil is found a whitish exudation, and the patient experiences slight difficulty in swallowing which may last from a few hours to two or three days. The wound is completely healed in the course of eight days.

On the ground of the fifty cases treated the author formulates the following conclusions:

1. Strangulation of the tonsils by means of the cold snare is an easy procedure and attended by but little pain, even without the use of cocaine.

2. Although not the only method for removal of the tonsils, it is especially indicated for nervous children, and in cases of greatly enlarged tonsils.

3. This method is contra-indicated where the tonsils are incarcerated or extended too far beyond the faucial pillars.

4. The hemorrhage is often much slighter if the operation is performed slowly; at any rate, it is not more profuse than under the use of the tonsillotome or knife. It usually ceases within a few minutes; and should this fail to occur, it can be arrested by application of a small cotton tampon medicated with equal parts of iodoform and tannic acid.

5. The cold snare has the following advantages over the tonsillotome: (*a*) It is less likely to provoke fright in children. (*b*) It is a less costly instrument. (*c*) It can be more readily cleansed, and hence is more aseptic, especially if a new wire is used for every operation. (*d*) The removal of the tonsils is more thoroughly effected, although much less rapidly than with the tonsillotome.

6. The cold snare is to be preferred to the knife, because it requires the use of only one hand and does not produce injury of surrounding parts.—*Wien. Medic. Press.*

Fractures of the External Condyle.

Dr. F. E. Bunts summarizes his views as follows: Fractures of the external condyle are confined almost exclusively to children, and are usually the result of direct injury. Displacement of the fragment may take place in any direction except inward, and is sometimes accompanied by a dislocation of the radius and ulna. While good motions may generally be anticipated, anchylosis either partial or complete is of frequent occurrence. An unusual prominence of the upper end of the fragment, widening of the joint, increase or decrease of the carrying angle of the forearm, may result under any treatment. No dogmatic line of treatment should be insisted upon. Early passive motion should be resorted to. The prudent surgeon will at once inform his patient or patient's parents of the nature and probable consequences of the case, and refuse to promise them under any consideration that a perfect result will occur.—*Med. Age.*

Congenital Ptosis.

Dr. Mary Putnam Jacobi presented a baby with congenital ptosis. At birth, the eye had been completely closed, but subsequently the ptosis had become partial. It differed from cases of this kind previously reported in being unilateral. The condition is quite rare, and in most instances the recti muscles are involved, which is not true of the present case. In a case described by Schenckel all the ocular muscles were imperfectly developed, but accommodation was perfect, as was also the response of the pupils to light. In another report, mention is made of two members of the same family being affected in this way. Gower speaks of combined paralysis of the facial and abducens as being rather more common than paralysis of the oculo-motor nerve. The question of the syphilitic origin of this condition naturally suggests itself, but there seems to be no reason for suspecting such a constitutional taint in the case just presented. It is possible that it may be one of the parasyphilitic lesions. The speaker said that so far as she knew, the only attempt to remedy this condition had been made by Evans, of Louisville, who had operated upon a case of bilateral ptosis according to a method devised by Pannus. In brief, this consisted in taking a flap from the lower part of the eyelid, and uniting it to the occipito-frontalis muscle, the object of the operation being to make this muscle take the place of the missing levator. The result in the case reported has been fairly satisfactory.—*Archives of Pediatrics.*

Local Therapeutics of Phenacetine.

Although phenacetine has been chiefly utilized for internal administration as an antipyretic, antineuralgic and sedative, evidences are at hand showing its great value as a topical remedy in various diseases. In an article read some time ago before the Tennessee State Medical Society, Dr. M. H. Lee reported a number of cases of ulcers in which remarkable results were produced by the application of finely powdered phenacetine. The ulcers were of traumatic and specific character, and had resisted external and internal treatment. Under the application of phenacetine, however, immediate improvement was effected, pains, if present, being at once relieved and granulations appearing rapidly. Dr. D. Coit Taylor, of Providence, R. I., (*Med. World*) has obtained excellent results from the local employment of phenacetine in the treatment of rheumatic pains of joints, pains from sprains, contusions or bruises, and recommends the following formulæ:

Phenacetine..... ..... gr. 15–20
Spts. vini rectific.—Aquæ bul.. āā 1 ounce

Sig.: To be applied on cloths as hot as can be borne.

Phenacetine..... gr. 15-20
Lanoline..... 1 dram

M. Apply by manipulation.

According to the *Journal de Medecine de Paris* (*Therapeutic Gazette*) useful results are obtained in cases of acute rheumatism by applying phenacetine externally to the painful parts. The following prescription may be used:

Phenacetine..... gr. 75
Lanoline..... 6 drams
Olive oil..... a sufficient quantity

To be rubbed about the inflamed parts.

Phenacetine..... gr. 75
Alcohol..... 2 pints

In this solution dip compresses and apply to the painful parts.

Internal Hemorrhoids.

Dundore, after an exhaustive paper on the subject of internal hemorrhoides, concludes as follows:

1. The ligature is the safest method of operating for internal hemorrhoids, as there is less likelihood of its being followed by hemorrhage, stricture, or ulcers.

2. The clamp and cautery cause less pain, shorter convalescene, and are less likely to be followed by retention of urine than when the ligature is used; but hemorrhage and stricture of the rectum may very often follow their improper application.

3. The practice of Whitehead's method should be limited to those cases in which the entire circumference of the anus is involved. In ordinary cases of one or more hemorrhoids it should never be used, as it is liable to be followed by severe after-effects, and at best could produce no more radical result than the clamp and cautery or ligature.

4. Simple dilatation of the sphincter, injection of carbolic acid, and Manley's method are simple palliatives, and their use is very limited.

5. There is no single operation which is available in all cases. Experience alone should suggest the most efficient method of treating each individual case. — *Mathews' Medical Quarterly.*

Fractures of the Humerus at the Elbow Joint.

Dr. C. W. Dulles calls attention to the point in the management of the fractures of the humerus at the elbow joint that if the forearm be semi-pronated and fully flexed upon the humerus, the head of the radius and the coronoid and olecranon processes of the ulna will hold the inner and outer portions of the lower end of the humerus in a correct anatomical relation to each other and to the bones of the forearm. To meet these indications he applies from the fingers to the shoulder, smoothly and with moderate tension, a soft flannel bandage, avoiding undue pressure upon the anterior angle at the elbow by having the forearm flexed and semi-pronated while the bandage is applied. After this the bend at the elbow is filled with some cotton, a splint is laid against the arm with very moderate cotton padding—not bound on with a bandage, but just laid loosely on—and the whole is enclosed with a good roller bandage. Any splint may be used which will maintain the forearm in full flexion upon the upper arm. For this purpose a splint with a very acute angle, to fit either side of the arm, or an anterior angular splint will answer—*Boston Med. and Surg. Jour.*

Treatment of Ulcers of the Leg.

Frank (*Jour. of Amer. Med. Asso.*) treats these cases as follows: The granulations are thoroughly cleansed at first. Then they are treated with silver nitrate if the granulations are hypertrophic, or with iodoform if the surface is putrid, torpid and lacking in vitality. The leg is then washed and shaved, and a moderately thick layer of warm gelatine is applied to the ulcer with a brush. The gelatine is thus prepared:

Oxide of zinc..... 30 parts
White gelatine..... 40 "
Glycerine..... 50 "
Water..... 90 "

A small patch of gauze is added as a covering and a gauze bandage from the toe upward. If you want firm dressing, cover the bandage with another layer of gelatine, and continue the bandage from above downward; let the gelatine cool and dry. If the discharge is abundant repeat the dressing every fourth day. If it is less, keep it on for eight days.

ORIGINAL ARTICLES.

A FATAL CASE OF PELIOSIS RHEUMATICA COMPLICATED BY MALIGNANT ENDOCARDITIS.

W. HENRY PRICE,† A.M., M.D., PHILADELPHIA.

Hemorrhages under the skin occur under such varied circumstances that it is somewhat difficult to separate them into individual groups as one variety often merges so close into another, but clinically three distinct forms have come to be recognized as having sufficient differences to warrant their being called by individual names. To these three varieties of subcutaneous hemorrhages the generic name of purpura has been given, and they are distinguished from one another according to the severity of the symptoms, their supposed etiology and the gross appearance of the spots, by certain adjectives.

The first and mildest form is purpura simplex, which consists usually of small scattered petechial spots appearing upon any part of the body, but most frequently upon the arms, neck and trunk; the cause of which is very undetermined, the affection giving no subjective symptoms, and most often needs only to be differentiated from flea bites by there being no central point of injury in the former and the redness does not disappear on pressure. Recovery from this form is the rule, though our prognosis must be guarded, owing to the possibility of complications.

The second variety is that known as purpura rheumatica, or peliosis rheumatica, in which the cutaneous hemorrhages constitute the chief feature of the disease, although there are accompanying symptoms, such as vomiting, abdominal pain and severe pains in the joints, which are so like the manifestations of arthritic rheumatism as to frequently make it most difficult to distinguish it from the latter, especially when the joint symptoms precede by several days the appearance of purpuric spots. Its course is often obscure, as it not infrequently arises in the midst of apparent health, though in some cases it follows hepatic derangement, while in other instances sudden nervous shock or prolonged mental worry has been noted as a causal factor in its production. In the case about to be described both congestion of the liver and prolonged mental anxiety preceded immediately the onset of the attack. The tendency, however, of late years has been to consider an infectious microbe as the cause of peliosis rheumatica—just as many observers, such as Whittaker and others, believe that acute rheumatic arthritis is an infectious disease. Thus Letzerich found a bacillus which caused hemorrhages when injected

† Physician-in-chief to the Childrens' Clinic of the University Hospital; Visiting Physician to the Baptist Orphanage at Angora and Physician to the Out-patient Department of St. Clements Hospital, Philadelphia.

into healthy rabbits, and Petrone produced the same result by injecting blood from a purpuric patient, and still other investigators corroborated these experiments. Hanot and Luzet, as quoted by Hardaway, found in a foetus, the mother being dead of purpura, streptococci identical with those found in the mother. Though too recent to be relied upon, these observations suggest that some cases of purpura may be acute infectious diseases, and this idea is borne out by the clinical history in many cases, such as the writer's own, where there followed as a complication a malignant endocarditis, an affection admittedly of microbic origin.

The third and most severe form of purpura is purpura hemorrhagica (Morbus Werlhöffi) which presents in addition to cutaneous hemorrhages, bleeding from the various mucous surfaces, and at times hemorrhage into the internal viscera, the most rapid death being produced by a bleeding into the brain substance.

The prognosis in the last two varieties of purpura is always grave.

Without discussing the subject further from a didactic standpoint, I record the following case.

The patient was a large, well-built man of thirty-nine, superintendent of public schools in one of our New Jersey cities. For several months he had been under great mental anxiety about domestic affairs. He showed an evident lithæmic diathesis and suffered occasionally from sick headache, probably averaging one attack a month, but never accompanied by vomiting. Aside from this his general health had been always good, except an attack of enteric fever some twelve months previous, in which simple albuminuria was present. He suffered a relapse lasting two weeks, with a temperature reaching as high as 105½°.

Two months before his last illness he had a siege of diarrhœa, lasting about four weeks, with black stools.

I saw him for the first time on September 4th. Upon September 2d he felt chilly all day and at midnight severe bilious vomiting ensued, lasting nearly two hours almost continuously, the vomited matter being very bitter. The temperature, taken soon after, was 104½° and later fell to 102°.

The following morning a small purpuric spot made its appearance upon the right side of the second phalanx of the right middle finger. The temperature was then 101°. There was little or no itching, but a slight burning pain, and the spot increased in size rather rapidly, until by night it measured one-third of an inch in diameter, and by this time showed a white central point. The lymphatic from this area leading up the side of the finger was inflamed, so that its course could be distinctly traced. During this same day he complained of marked pain in the right ankle and right wrist joints, both of which were slightly swollen, and the pain was greatly increased by either active or passive motion.

At the next visit, which was on the morning of the third day of the disease, numerous other spots had made their appearance—sixteen being counted upon the left hand and seven upon the right. All were small, non-elevated, purplish in color and varied in size from a pin's head to one-quarter inch in diameter. The larger spot before described, with white centre, was laid open and a scraping placed on a slide under the microscope showed the white central portion to be pus cells, and the surrounding purplish-black pigment, scraped and placed on a porcelain tablet, responded to the test for bile by showing a well-marked iridescent play of colors with a drop of fuming nitric acid. This seems to be a new feature about the manifestations of rheumatic purpura, as I am unable to find any record of bile being recognized in such spots, even where, as in this case, the attack followed immediately an acute derangement of the liver. Of course one might ask did not this apparent bile reaction really come from the presence of hæmatin, derived from decomposed hæmaglobin. The detection of this bile, however, lead to a careful examination of the liver, urine and feces. The liver was enlarged, tender and at times during this first week so painful as to require turpentine stupes. The urine was laden with bile, responding distinctly to three different tests, and the stools were clay-colored. Here then the blood must have been saturated with bile, and why should not a purpuric spot, making its appearance at such a time, show bile also?

Up to this time the patient, from a combination of ambition and general restlessness, had refused to remain in bed, but

upon the following morning on awakening the left wrist-joint also was painful and swollen so he consented to remain at rest and the three painful joints were wrapped in wool and cotton, and he was given internally ten grains of salicylate of soda every two hours in conjunction with digitalis and phytolacca. After the eighth dose it was to be reduced to once in three hours, and on the following day an ointment of equal parts of belladonna, ichthyol and lanoline was applied to the joints twice daily. Under this treatment the temperature gradually came down and at the end of three days it was normal. The heart had been carefully auscultated every-day and up to this time it was quite free from murmur and both sounds were clear and normal. But at 3 A.M. on the morning of the eighth day of the disease, he had a severe chill lasting ten minutes, followed by a high fever and copious sweating. At 3 P.M. a more severe chill and a temperature of 105° and one hour later sweating. At 3 P.M. the next day another chill; temperature 103½° and sweating. This was repeated again at the same time the following day. He was given fifteen grains of quinine in three doses, and on each of two succeeding days thirty-five grains, during which interval he had no chill, but a free epistaxis, and this was repeated five times the day folfowing. The pain and swelling in the joints gradually decreased but he was still quite helpless. Meanwhile another and last purpuric spot made its appearance on the left elbow, about the size of a silver quarter-dollar, with a white center, which increased peripherally until the whole spot became purulent, finally discharged and then dried up. After this the bile disappeared from the urine (which at no time contained any albumen) and the stools become normal. On the evening of the fourteenth day the temperature rose to 102½°, followed by profuse sweating, but it was not preceded by a chill. Tinnitis aurium present. Afternoon of next day wakened from sleep, not knowing where he was and ideas greatly confused, but not a true delirium—temperature 103 3-5°. Believing these symptoms to be due to the quinine and salicylate, they were stopped, and in twenty-four hours all head symptoms disappeared and he was quite rational again. In a day's time, however, he suffered another chill with fever and sweating, and at this visit a distinct diastolic murmur was present for the first time, which was heard loudest at the second right costal cartilage and transmitted down the sternum—in other words, an aortic regurgitation. At no time had he complained of præcordial distress or pain, and the pulse remained unchanged. Morning temperature 101½°, falling to normal by noon, and patient feeling better and brighter, the right wrist alone remaining painful and slightly swollen. Treatment then was acetate of potash, infusion of digitalis and deodorized tincture of opium.

The next afternoon the patient wakened up in delirium, and the thermometer registered 106½°. At the evening visit it was 104° and by midnight it had fallen to 100 4-5°, his head being somewhat clearer, but a new heart complication, a mitral systolic murmur, was detected. At 8 A.M. the following morning the temperature was again 106½° and the murmur was more distinct.

The treatment was again modified by adding ammonium benzoate and quinine, each five grains thrice daily, to the potassium acetate mixture, but with no beneficial effect, of course, as the case now was one evidently of malignant endocarditis.

The disease ran on for eight days longer; chill, fever and sweat recurred at more or less regular intervals; head symptoms reappeared and symptoms of general septicæmia manifested themselves, until finally the patient succumbed to the ravages of the staphylococcus pyogenes and its toxines, and died four weeks after the initial symptoms of the hepatic derangement. No autopsy was allowed.

A summary review of this case suggests the following thoughts :

I. Prognosis in peliosis rheumatica should always be very guarded.

II. Corroborative evidence is offered to support the theory that this disease is due to an infectious microbe.

III. That the similarity of the symptoms and sequelæ of this disease and of acute articular rheumatism may be due to their both having this infectious origin.

IV. The tendency toward bleeding from the mucous surfaces, as in this case in the occurrence of copious epistaxis, suggests a close relationship between rheumatic purpura and purpura hemorrhagica.

V. That the liver symptoms may have

been due to an infectious congestion from which organ the cocci were distributed by the general circulation to the heart and peripheral capillaries.

VI. In this, as in true rheumatic arthritis, full doses of the salicylates afford, perhaps, the greatest relief to the pain and swelling of the joints.

NOTES ON HYPNOTICS.

J. E. McCRAIG, M.D., PROVIDENCE, R. I.

Among the older medicaments, perhaps no class gave less satisfaction than the hypnotics. Opium and its salts, when given in safe doses, are unreliable as sleep producers. Chloral is dangerous, especially in those cases where its hypnotic action is most urgently desired, where the heart muscle is deteriorated by the strain of long-continued insomnia and lack of nourishment. Both are undesirable from their tendency to habituation. Hyoscine often fails and is always dangerous. The bromides are not sufficiently powerful to be of great practical use, and their depressing effect, when long-continued, makes them undesirable. The newer drugs of this class have given better satisfaction, and although the literature of trional and sulfonal is fast becoming quite extensive, the following notes of cases may not be without clinical interest. They are selected from a number of cases in which these drugs were exhibited, as showing the results under different conditions.

CASE I. Acute delirious mania. A. M., female, aged twenty-three years, Irish; temperature 103° F., pulse 130; respiration 30; tongue brown and dry, teeth covered with sordes; intense motor excitement; incoherent. Had been given morphine and hyoscine hypodermically to produce sleep, but unsuccessfully. Had slept but one hour in the last seventy. Given sulfonal, 1 dram in hot whiskey at 9. P.M. Next morning was quiet after having slept 3 hours. Temperature 100° F., pulse 120; respiration 25. Sulfonal repeated at 9 P.M., after which she slept 5 hours.

This treatment, together with stimulants, tonics, etc.; was continued for thirty days, and she eventually made a good recovery. After the first dose the urine was retained, requiring the use of the catheter for three days.

CASE II. Chronic melancholia. C. B., female, aged seventy-four years, American; temperature and respiration normal; pulse 80; arteries atheromatous, urine normal. Had been taking nightly doses of chloral, gr. xl., for twelve years. Became agitated, and chloral failing when given in reasonable doses, was given sulfonal, gr. xxx, which gave eight hours good sleep. This was continued for three months, during which she improved physically, though no mental change was manifest. At the end of that time trional was substituted in 30 grain doses, which were gradually reduced till six months later she slept fairly well on 7 grains nightly. In this case also the urine was retained, requiring catheterization for 48 hours after the first dose, the drug being continued.

CASE III. Acute melancholia. S., female, aged fifty-seven years, American. Attempted suicide by opening the left radial artery with a pen during the night and bled to syncope. Twelve hours later went into a condition of frenzy, biting, scratching, tearing off her clothing and attempting to injure herself and all about her. At this time the radial pulse was imperceptible. Was given trional, gr. xl, in hot whiskey by the nasal tube, and as she was still violent was given 10 grains more in 15 minutes. Was asleep in 15 minutes after the second dose. Slept 18 hours and awoke quieter. During her long sleep she was awakened to take nourishment once, immediately drooping off to sleep again. At no time were there any untoward symptoms. She finally made a good recovery mentally and physically, trional being given as required to produce sleep.

CASE IV. Acute delirious mania. C. S., female, aged seventeen years, American; temperature 102° F.; pulse 130; respira-

tion 30. Tongue dry, brown and cracked; sordes in the mouth, herpes on lips. Had neither food nor sleep for three days before admission; given trional, gr. xl, and slept 3 hours. Following night slept five hours on the same dose. On the third night, the dose was reduced to 30 grains, on which she slept 6 hours. The drug was gradually reduced to 10 grains nightly, with which she got a good night's rest. She is now convalescent.

CASE V. Acute mania. A. M., female, German; aged forty-three; temperature 99; pulse 100; respiration normal; mitral regurgitation, compensation fairly well maintained. For insomnia, was given morphine hypodermically without satisfactory results. On account of the cardiac condition sulfonal was given cautiously, the initial dose being 20 grains. The first two nights the patient slept very little, but on the third slept all night. This condition was continued for a month, the heart being carefully watched, but no ill effect was observed. She became chronic and died two years later.

CASE VI. Approaching climacteric; M. J. F.; female; aged forty-seven; American; sane. After an attack of dysentery suffered from insomnia, which was assigned to domestic anxiety. Derived good effect from nightly doses of 15 grains of trional, and upon attaining a better frame of mind a month later, abandoned the use of the drug without any trouble.

CASE VII. W. M.; male; aged thirty-two; American; druggist; family history phthisis. Patient suffered from indigestion and insomnia aggravated by business worry. After a sleepless night took 15 grains of trional at 2 P.M. and attempted to sleep. Half an hour later took 15 grains more and was asleep in fifteen minutes. At 7 P.M. he was awakened and, though feeling some giddiness and slight nausea, attempted to do his usual work. When seen at 9 P.M. he had been vomiting, face cyanotic, extremities cold, perspiration profuse, temperature sub-normal, pulse 120, very small and weak. Consciousness was unimpaired and the patient complained of nothing but nausea and cold. He was treated with stimulants; strychnine and nitroglycerine hypodermically, and warmth externally. He soon rallied and slept comfortably all night. He was confined to bed for three days, complaining of nausea upon trying to rise. For some time subsequently he complained of irritability of bladder, and traces of sugar and largely increased urates were found in the urine.

It will be noted that in cases 1 and 2, in which sulfonal was given in somewhat large doses, retention of urine followed the first dose. My former colleague, Dr. Chas. B. Mayberry, of the State Hospital for the Insane at Danville, Pa., has kindly furnished me with notes of a case of maniacal excitement occurring in a paretic dement of one year's standing, in which two 1 drachm doses were given upon consecutive nights. After the second dose the urine was retained and had to be drawn by catheter. In this case, as in one of the former, the urine was normal in quantity and character. In one it was ammoniacal. None of these patients presented histories of retention and they have since had no trouble. I have not been able to find any reported cases of this trouble following the use of sulfonal, but in all these cases we were able practically to exclude any other causation.

In case 7 the ill effects might in some measure be due to the interruption of sleep. I have never observed anything similar following the use of trional in other cases, and I have used it quite extensively both in sane and in insane patients.

It is but fair to state that in the cases quoted I have included all those in which I ever observed any ill effects from these drugs, and omitted as lacking in interest those routine cases in which they were a source of comfort both to patient and physician. In my opinion we have in sulfonal and trional, but especially in the latter, many of the qualities which go to make the ideal hypnotic. Reasonable safety, reliability and freedom from unpleasant after-effects and the tendency to habituation.

APPENDICITIS.*

J. CHRIS. LANGE, M.D., PITTSBURG, PA.

In March, 1893, I reported to this society, *in extenso*, fifteen cases of appendicitis, with recovery in all without operation and without suppuration in any except one case, which terminated in an abscess which was incised without anæsthesia and drained, leaving a sinus which healed three weeks later.

This list comprised all cases treated by me rom 1875 up to the date of the report in which the diagnosis was indisputable. All suspected cases were excluded. The criterion determining admittance to or exclusion from the list, was the presence of a fixed tumor in the right iliac fossa irrespective of how pronounced might be the other symptoms of the disease. It is unnecessary to say that doubtful cases not in the list ended in recovery.

I have now to report to you three additional cases ending like the others in recovery, without operation and without suppuration.

CASE XVI.—March 25, 1893. Male, age twenty-seven. Diarrhœa with pain and nausea on previous day. Induration distinct and painful March 27th. Morphine and calomel one-eighth grain of each every third hour, continued until eighth day, when diarrhœa ensured and morphine and bismuth were given. Tumor gradually decreased in size and was lost April 20th. Patient has since been well.

CASE XVII.—May 3, 1893. Male, age seventeen. Vomiting and nausea two days. Constipation and pain in right iliac fossa. Tumor very tender; feels as long and thick as about three fingers; longitudinal axis coincident with that of colon. Calomel and morphine one-eighth grain each every three hours. Considerable tympanites. Powdered charcoal was given in large quantities; also iodoform in three grain doses four times daily for three days. Vomiting ceased after second powder of calomel and morphine. Tympany moderated after fourth day of treatment. Tumor now very perceptible, is hard and well defined. Upon the eleventh day of treatment, first movement of bowels. Three additional movements same day. Tumor perceptibly decreased in size. Morphine and calomel discontinued. Patient desires to arise, but is kept in bed as long as any induration can be felt and receives five grains of subgallate of bismuth every six hours. Light diet and no other medication. Tumor steadily decreasing in size until June 10th, when patient is allowed to leave his bed.

CASE XVIII. Male, forty-five years of age. Was seized upon the street with faintness, vomiting and great pain in region of navel, October 14, 1894. Was carried into a neighboring house and from there removed to his room at the German National Bank. Temperature 102½°. Pulse 120. Was given one-eighth grain calomel and morphine every three hours, and on the 16th was removed to West Penn Hospital. Tumor very distinct; long, narrow and tender. For tympanites was given five grains of subgallate of bismuth. Morphine and calomel continued until 14th day, when for the first time there was a passage from the bowels and at the same time an elevation of temperature, which for seven days had been normal, to 102°. This temperature being maintained upon the 14th, 15th and 16th days of the disease, during which time he had one or two stools daily, I decided an operation necessary. After consulting with Drs. Murdock, Macfarlane, Cameron, Hiett and others at the hospital, 11 o'clock, November 3d, was fixed for the operation; this being the 17th day of the disease. Patient that night was again given one-eighth grain of morphine every third hour with five grains of subgallate of bismuth. He presented at the time for operation a condition so much improved in every respect that my associates who again saw him, agreed that operation

*Read before the Allegheny County Medical Society, December 18, 1894.

was uncalled for. After this time he had no temperature elevation; his tumor grew steadily smaller, and he was dismissed November 22d.

The very considerable progress in the etiology and pathology of appendicitis recently made, throws a new and much brighter light upon this disease than we before possessed; and much strengthens a suspicion that appendicitis frequently is, and always may be made a surgical affection by improper treatment. It gives to the "foreign body" etiology its death-blow and answers the questions: Why, as a vermiform appendix corresponds so closely in structure with the rest of the intestine, is it so frequently the seat of disease as compared with the other portions of this tube? Why, as the same pathological laws govern the appendix as govern the other tissues of the body, do they assert themselves here so much more frequently than elsewhere? The "foreign body" etiology can no longer hold its former rank. It rested upon error and the possibility of always finding fæcal concretions in the appendix or in the abscess resulting from its inflammation, at every operation. It is now established that identical fæcal concretions are found in almost every appendix in bodies dead from all causes; and also in almost all laparotomies done for other diseases. In other words, these fæcal concretions are contained in all appendices favorably conformed for their capture and imprisonment; *i.e.*, the vast majority. They are therefore innocent in the production of inflammation in the appendix as in other parts of the intestine.

Dr. George R. Fowler, in operations embracing more than two hundred cases, found foreign bodies, or anything that could be construed in any sense foreign, in but two cases. One of these was a gall-stone, the other an enterolith of calcareous salts. I quote from Dr. Fowler's recent work: "The etiology of appendicitis was supposed in former times to involve the presence within the appendix vermiformis of cherry stones, grape seeds, lemon and orange pips, date stones, fish bones, pins, etc.

"This belief seems to have been based upon evidence which is deemed insufficient by scientific men of the present day, although it is not denied that traumatic appendicitis may occur.

"The belief that the disease is frequently due to the engagement of foreign bodies in the cavity of the organ is based, to a large extent, upon purely speculative or imaginary conditions. In all probability the notion that cherry stones, lemon and orange pips, or date stones are largely responsible for the occurrence of the disease is based upon the fact that the little masses of fæcal matter which have been moulded into shapes accurately representing these bodies are found during the evacuation and irrigation of an appendicular abscess. It has happened more than once during an operation of this character at my hospital clinic, that one or another of the bystanders has exclaimed, as the little mass of fæcal matter came into view, 'a lemon pip,' or, 'a date stone,' so strong a resemblance was there between these masses and the bodies mentioned. In every instance, however, the fact was that they were, with the above mentioned exceptions, made up of moulded fæcal matter as was demonstrated by simply flattening them out between the thumb and finger. Beyond the little masses of fæcal matter which become imprisoned in the cavity of the appendix by the occurrence of constriction, either at the point of communication with the cæcum, or at some other portion of the tube nothing in the shape of a foreign body, other than those mentioned, has been found in my experience to account for the conditions present.

"The ease with which fæcal matter may retain its position in the cavity of the appendix may be easily understood when the facts in the anatomy of the organ are borne in mind. These are:

"First, the fact that it usually occupies a dependent position in the large majority of cases; hence gravity alone will aid the passage of fæcal matter into its interior, and also favor its retention there.

"Second, The absence of well-marked circular muscular fibres gives rise necessarily to a very feeble expulsive power. Hence it may be said that the appendix vermiformis does not have that inherent power of emptying itself which other hollow organs, supplied with longitudinal and circular involuntary muscular fibres combined in proper proportions, possess.

"In addition, anatomical studies and clinical experience (examinations made of healthy appendices during laparotomies)

unite to support the assertion that fæcal matter is found in a considerable number of appendices in individuals who had never suffered from the symptoms of appendicitis.

"The mere presence of masses of fæcal matter, therefore, cannot be looked upon as necessarily producing the disease, even though these become more or less hardened by inspissation. This hardening process takes place after their imprisonment, and is due to absorption of the watery elements after the escape of the fæcal matter is cut off.

"In this condition they may, by their presence, produce in an already inflamed and partially devitalized organ, ulcerative changes, or even extensive gangrene, by still further interfering with the normal circulation. That they do not necessarily give rise to the disastrous perforation which is so frequently a marked feature of the disease is shown by the fact that they are not always present when this accident occurs. When they are present they are rarely found at the point of ulceration but are located, in the great majority of cases, either above or below the site of perforation. Moreover, cases are observed in which the entire outer structure of the appendix has sloughed away as a result of a violent inflammatory process, leaving the mucous membrane as an intact blind sac with fæcal matter in its interior. Whatever fæcal matter, either fluid or solid, chances to be present plays but an accidental role. It is not even necessary that these fæcal masses should produce either ulceration or even a lesion of the mucous membrane. As a matter of fact, their physical qualities are usually such as render it altogether probable that they produce no primary lesion; but that in their soft condition they may remain, for an indefinite period of time, within the tube without doing harm. That fæcal masses do occur within the cavity of the appendix vermiformis without the occurrence of inflammatory processes is proven by the frequency with which their presence is noted in post-mortem examinations, as well as in laparotomies performed for other conditions."

We must recognize from the relatively frequent occurrence of inflammation of the appendix a predisposing cause, which does not obtain in other parts of the intestinal tube; and recent anatomical and physiological peculiarities pointed out by Dr. Van Cott, Jr., and Dr. Fowler, as well as pathological and bacterial processes, make this quite definite.

The comparative anatomy of the cæcum demonstrates that in man the appendix is an organ of evolution; the rudimentary remnant of the lengthened cæcum found in all mammalia except in man; and as far as its origin is concerned, this is the natural result of developmental changes involving in intra-uterine life, the forward and downward enlargement of the cæcum. Further, the blood supply of the tissues of the appendix, the peritoneal, the muscular, the subcutaneous and the proper mucous coat, is a scant supply. This fact demonstrates a low tissue vitality. This is all the more true because the only nutrient artery of all these coats, which comes from an anastomosis between the mesenteric and colic arteries, allows the appendix a terminal circulation only. It is limited to this one artery. It can receive blood from no other source, because it and its branches anastomose with no other vessels. Because its circulation can receive no assistance when this becomes necessary; because no collateral circulation can be established in these four coats of the appendix, they are necessarily liable to the consequences of deficient blood supply which involves a low tissue vitality and a lessened power of resistance.

It is this which is the predisposing cause of appendix disease; in further proof of which it is important to note that in females the appendix has a slight additional blood supply, namely, through the appendiculo-ovarian ligament; and that this constitutes the only discoverable reason for the proportion of cases of appendix disease; namely, twenty per cent. for females and eighty per cent. for males.

The certainty that the appendix, as no other structure in the abdomen, is peculiarily susceptible to inflammation is explained therefore by the comparatively low vitality of its tissues which determines changes in their nutrition and inability to resist all manner of attacking agents. When to this natural predisposition is added one or other of the determining or direct causes, then inflammation of the appendix tissues happens.

The direct causes of appendicitis, quite unable to act in other portions of the in-

testinal tube because of their better blood supply and their consequent better nutrition and greater power of resistance, and for the same reasons able to act only in the proportion of one in females to four in males, are *torsion of the appendix and infection by the bacillus coli communis.* Infection alone is adequate to inflame the appendix tissues. When torsion is the process which, added to the predisposing cause, causes the inflammation, then infection is soon added.

It is to be remembered that the tip of the appendix is free, movable by its own peristalsis and also by the peristalsis of its contiguous intestinal coils; by changes of their calibre and position the appendix is subjected to alternating pressure and freedom from pressure and to changes in position as well as to flexions, distortions, angulations and twistings very slight degree of which, quite inadequate to do this in other portions of the intestines, are competent here, because of the low vitality of the tissues, to induce nutritive changes ending in appendix disease. This they accomplish by inducing blood vessel alterations, sometimes thrombosis, sometimes chronic connective tissue hypertrophy of vessel coats, and by degenerative changes in the trophic nerves. These changes have been found in certain cases to have their beginning not in the appendix tissues themselves, but extending to these from the meso-appendix. After the development of these changes for a longer or shorter time, probably for years, they interfere with the nutrition of the appendix to a sufficient degree to cause inflammation, gangrene, or probably much oftener, connective tissue hypertrophies and contraction of appendix tissue. These chronic vessel and nerve lesions are accountable for the frequency of appendix diseases primarily and give opportunity, by devitalization of appendix tissues, to the pernicious action of the always present bacillus coli communis. This infection is facilitated further by the retention in the appendix of the product of its mucipa-rous glands, some serum and perhaps some fibrin, these substances forming an excellent culture medium for the bacillus and also inviting and entertaining the pus-forming cocci, which together with the bacillus coli communis are found in appendicitis always when pus is present for which the cocci are indeed responsible.

The same result is obtained by the bacillus coli communis without the aid of angulation, twisting or pressure upon the appendix tissues, whenever from thrombosis or arterio-sclerosis or neuritis the appendix tissues reach a sufficient low vitality to be unable to longer resist penetration, multiplication and toxine formation on part of the bacillus coli communis, always present in the appendix, as in the intestine at large.

Hodmypl has shown that this microörganism is present in the intestinal canal in health; is discharged with fæcal evacuations constantly and exists always in the appendix. It would take rank therefore, with the non-pathogenic bacteria were it not that under certain tissue conditions its behavior is most virulent, inasmuch as it is readily assisted in the production of lethal lesions by the early advent of the pus-forming cocci.

Among the tissue changes favorable to penetration, multiplication and toxine formation on the part of this organism, is that of the tissues of the appendix—a low vitality. A vitality which may be designated normal and which exists throughout the tissues of the intestines elsewhere, keeps the bacillus non-pathogenic; the vitality of the appendix tissue, however, which is below normal, allows it to become pathogenic because of decreased resistance to its tendencies. These tendencies are to penetrate the mucosa; to multiply and form absorbable toxines in the sub-mucosa, and to reach the peritoneal coat and the cavity through the muscularis; and, superadded to this, to call to its aid the pus-forming cocci for the production of abscess.

The bacillus coli communis is found in the peritoneal cavity upon the serous covering and the adhesions of the appendix; and also, in conjunction with the pus-forming cocci in every appendix abscess. The question of abscess, or no abscess, hinges, therefore, upon the ability of the bacillus coli communis to bring to its aid, in its destructive efforts, the pus-forming cocci; and the important consideration is this, can treatment prevent the advent of the cocci, thus limiting an inflammation of the appendix to the exudation of fibrin and serum, which happens because of the activity of the bacillus communis alone?

In other words, can medical treatment limit the inflammation to an adhesive one?

Can medical treatment be responsible for pus formation? The last question I venture to answer with: Yes, medical treatment of appendicitis can determine pus formation.

I cannot proceed to any remarks upon the treatment of appendicitis without mention of its surgical side, because the discussion which is to follow has been usually devoted to the question of medical or surgical treatment almost exclusively. As this question may for once be ignored, and the medical treatment discussed with more time and profit, at least to me, I concede to surgery the following: Every appendix abscess demands operation. In all cases of doubt operation is indicated. The operation is comparatively safe when done by those whose surgical technique and modern methods have demonstrated the safety of their procedures.

How can the administration of medicine prevent the formation of abscess when this is possible, and what means and measures will most certainly induce pus formation in appendicitis, are the questions most interesting to me.

Autopsies and operations have demonstrated that in certain cases there is gangrene of one or more of the appendix coats, and also that these cases are rare. In 145 operations reported by Dr. Murphy, of Chicago, this condition was present 17 times. When present, it is unnecessary to say that medical treatment is vain. In a few cases there was a fibrinous exudate only, this number being about 12. All the others were cases of intra or extra-peritoneal abscesses, and, therefore, properly treated by surgical means. The time for medical treatment had expired in these latter cases. Medical treatment of abscess is vain. But medical treatment for the prevention of abscess is usually effective as shown by my list of cases. It, as a rule, will limit an appendicitis to a fibrinous inflammation only. This is accomplished by antisepsis of the intestinal canal and by rest of the tube. The object of the first is to destroy or to prevent multiplication of the bacillus coli communis, and the advent of the pus-forming cocci; the last to prevent, or to limit, as much as possible, the production of the inflammatory exudates which precede the advent of the pus cocci in the tissues of the appendix as everywhere else.

As my list of cases demonstrates, I have satisfactorily accomplished both of these objects by calomel and morphine. In the latter cases additional local antisepsis by guaiacol, iodoform, the subgallate of bismuth and charcoal was used in connection with calomel, which is a germicide acting, not only locally, within the tube, but also throughout the tissues of the body at large. In the earlier cases, when antisepsis was not understood; when it was not known that the beneficent power of mercury was its germicidal power; when it ranked as an alterative, and in inflammation as a sedative and an antiphlogistic, and was credited with the power of preventing or limiting inflammatory exudates, it was used for its then known effects. Now that it is understood how the specific treatment of syphillis by mercury is a germicidal treatment, and that the treatment by mercury of many and various conditions of disease in many and various tissues of the body is germicidal, this invaluable remedy finds many additional uses, and is employed in appendicitis as a general and constitutional antiseptic, penetrating the tissues and destroying or limiting the multiplication of the bacillus coli communis; endowing the epithelial and other barriers with a power of resistance which prevents penetration or multiplication in their tissues and the cavity of the abdomen. In addition and for the purpose of making the media in the intestinal canal as unfavorable as possible for the existence of all bacteria, guaiacol or iodoform, was given these patients, and when detension happened the subgallate of bismuth or charcoal.

Essential to the prevention of every case of appendicitis from a necessity for surgical interference, barring the rare cases of gangrene, is absolute rest of the bowels secured by morphine. No pus cocci can come, no abscess can form without a previous inflammatory exudate—serum and fibrin. The more violent the inflammation the larger is the proportion of serum and cells, the smaller that of fibrin, and vice versa. A fibrous or plastic exudate is favorable to organization, a serous exudate, corpuscular or croupous lymph, to pus formation. Absolute rest, the abolition of function of a part is, and always has been, known to limit the exudate of inflammation, to increase in this exudate its fibrin, or fibrin-forming elements, to

lessen in it serum and cells; in other words to make it favorable to organization, unfavorable to pus formation. This is true also of the appendix tissues. It is a medical as well as a surgical aphorism, as old as medicine, that inflammation requires first and always rest of the part, and this is as important in appendicitis as in any inflammation. Why does the surgeon splint the limb with extension in hip joint disease? Because, when done it limits the exudate, makes this fibrinous, unfavorable to pus formation. I have heard the questions asked: How can benefit come to a joint from rest and extension and counter-extension, when tuberculosis exists in it? How can quiet remove the tubercular tissue? The answer to these questions applies also to appendicitis. Rest fortifies all tissues; motion always involves waste; motion is always an expense; rest always a saving. In the hip-joint, when these tissues are taxed to withstand the grey tubercle or the yellow nodule of Virchow, the vitality of the tissues which is saved them by rest is the factor which enables them to encapsule tubercle, to make it innocuous, to prevent everything but a fibrinous, or, if still milder, a productive inflammation with no result but a temporary ankylosis. With this we are all familiar. We are also familiar with neglected cases of hip joint disease, in which the patient, not restrained in the use of his limb, and allowed to have this jerked by muscular twitchings during his sleep against the walls of his acetabulum receives the abscess and bone death which are so common. Here by the continued expense of motion to the tissues, these are unable to encapsule the tubercle; they are attacked by the tubercle plus the motion, and this combined expense they cannot cover. From want of ability to resist both these factors these tissues are devitalized and their blood vessels exude much serum, many cells, and little fibrin, and then invite the pus-forming cocci to peptonize them. This is the manner of formation of an abscess in hip-joint disease from want of rest. The manner of formation of abscess in appendicitis is identical, if for the bacillus tuberculosis be substituted the bacillus coli communis. Rest is as important in the one case as in the other. When it is possible to prevent pus formation rest to the part is an imperative and necessary factor of treatment. For this reason my cases all receive morphine, not for pain, except as necessity may dictate, but for the abolition of peristalsis; for the purpose of limiting exudation, which so limited is an adhesive inflammation only; an exudate of cement *i.e.*, fibrin; or if more chronic a productive inflammation, both innocuous and not corpuscular lymph which precedes and invites the pus-forming cocci. As my list of cases shows this may be accomplished, if not always, certainly, usually. Now as certainly as a tubercular hip joint will go on to pus formation if motion of the joint be not abolished, so certainly will purgation in appendicitis produce pus. The same is true of enemata, high or rectal, because all will move the contents of the bowel, agitate it and cause peristalsis. It is my firm conviction that no better method to prepare appendicitis for the surgeon can be employed.

If even the foreign body etiology were not now understood to be erroneous, how improbable, impossible, it must be recognized to be, that purgation can remove the offending body in the appendix held by secretions and inflammatory products and in a cul de sac. What possible advantage then can come of purgation?

Error alone, a misconception of pathology, the belief that the tumor or swelling consists of an accumulation of fæcal matter can, I conceive, be the only excuse for purgation. The tumor does not consist of fæcal matter in the appendix or cæcum, but of infiltration of the tissues and of the exudate within and upon them, and it can never be purged or washed away nor lessened by purgation or enemata. On the other hand, what injury can come from confining the contents of the bowel for any reasonable period of time when the gases of fermentation are absorbed by charcoal, fermentation is prevented by the subgallate of bismuth and the whole contents of the bowel kept innocuous by antisepsis?

As the primary cause of appendicitis, namely a low tissue vitality, is universal; as this is common to the human family; and, as when the appendix of any individual is once subjected to inflammation which, because this occurrence demonstrates a vitality low enough to produce it, is presumptive evidence that it will repeatedly inflame, there are but two con-

siderations which prevent assent to the proposition that an appendix once inflamed should be amputated. The first objection to this conclusion is that it cannot always be done. In Dr. Murphy's cases, 145 in number, it was removed in 60 cases; not removed in 68; and in 17 removal is not stated. No surgeon, no physician could fail to appreciate the necessity for operation in these cases. They were strictly not operations for appendicitis, if the twelve cases where the exudate was fibrinous be excepted; but on the other hand, operations for intra or extra-peritoneal abscess. In these cases it is seen, therefore, that presumptive future inflammation and its danger is not obviated by operation because of failure to remove the appendix in over fifty per cent. of these cases. Nevertheless, with the exception of the few who immediately died, the balance of the 68, still in possession each of his appendix, are presumptively cured. How unjust to not allow this term *cured* to apply to cases medically treated also; but to prophesy recurrecne because of the continued presence of the appendix.

The truth is that, and this constitutes the second objection to the proposition that the appendix once inflamed should be removed, in both the inflammations, medical and surgical, the nutrition of the appendix tissues is so decidedly altered, the tissues so decidedly changed, that the previous conditions rarely obtain. The more or less chronic inflammation of recurrent appendicitis, which is a productive inflammation, produce tissue requiring decidedly less blood than does normal appendix tissue; and the same is true of what remains of the appendix when it cannot be removed after a surgical inflammation. In either case it cannot be asserted that the previous causative low vitality of tissue persists.

Of the previous fifteen cases reported I have found eight, and in but one was there a recurrence, and it was so mild that medical aid was not summoned.

CHEMICAL AND BACTERIOLOGICAL CHARACTERISTICS OF MILK.

T. M. ROTCH, M.D., BOSTON, MASS.

There are certain questions regarding the chemistry of milk which, though not necessarily of vital importance to its use as a food, are still sufficiently so to make them worthy of our investigation. The first of these questions which I shall consider is the reaction of cow's milk both at the time when the cow is milked and later in its use for food preparations. This question of reaction is of so much greater importance in connection with the feeding of infants during their first year than for the later periods of life, that I shall discuss it with special reference to infant feeding. The importance of the subject lies in the well-recognized fact that the infant's digestive functions have been from time immemorial best adapted to the digestion of an alkaline or neutral fluid rather than to an acid one. Human milk has proved to be the food on which the greatest number of infants live and thrive during the first year of their lives, and on which the smallest number die proportionately to any other known food. Whether the moderately alkaline reaction of human milk is an important factor in the problem of infant feeding is a question which future investigation alone can completely prove, but with our present knowledge we are not yet prepared to dispense with even the least important of the many factors which make up this problem. At any rate we should be very suspicious of a breast milk which showed an acid reaction. In the preparation of food from cow's milk, according to the latest experiments by means of modification, the best results have been obtained from making the reaction of this food correspond to that of normal human milk. This, up to the present time, has best been done by means of the addition of an alkali, which is the only foreign element which it has been found necessary to employ.

My attention was first called to the pos-

sibility of obtaining an alkaline cow's milk corresponding in its reaction to that of human milk, by Mr. G. E. Gordon, who has by his extended and intelligent investigation of this subject carried on for so many years in the West, given such a stimulus to these questions of chemical interest. Many years ago it was noticed that cows fed on certain pastures such as occurred in Kentucky, represented by the Kentucky blue grass, and also in many other parts of the West, produced at the height of the season of such grass a product which was alkaline rather than acid, and which remained alkaline for a number of hours after milking. It is also, of course, well known that milk in general, wherever it is produced throughout the world has an acid or at least an amphoteric reaction. This information at once incited the investigation of the food values which existed in these peculiar pastures. Careful analyses showed that the nitrogenous elements of this grass had a certain proportion to its carbohydrates, namely, about 1 to 5½ (Kuhn.) It has also been noticed by this same class of observers, from whom we have derived the only real knowledge which we have of this subject that cows which are fed in their stall on comparatively dry foods produce a milk which is distinctly acid in its reaction. We would naturally suppose that by merely combining nitrogenous and carbohydrate foods in the proportion of 1 to 5½ the resulting product would resemble closely the product of the cows fed upon the pasture grasses already mentioned. This, to some extent, has proved to be true, but not so completely as is to be desired for the precision needed in infant feeding. It is therefore of the greatest importance to the solution of this question that experiments made in supplying the carbohydrate proportion of the food by feeding freely (ten pounds to each cow daily) with sugar beets of the highest saccharinity has accomplished empirically unlooked-for results.

The cows which were experimented with in obtaining these results were under observation for three months, and were cared for in the same barn and under the same general conditions. Two-thirds of this herd were fed on the ordinary food ratio of 1 nitrogenous to 5½ carbohydrates. The remaining third of the herd was also fed on the same ratio, but this ratio so far as the carbohydrates were concerned, was made up partly by Austrian sugar beets grown for this purpose. No beets were given to the first two-thirds of the herd just spoken of. During these three months when the experiments were being made the reaction of common litmus paper was constantly as follows: The cows fed partially on the beets showed neutral or feebly alkaline reaction, and the cows that received no beets showed a uniformly acid reaction.

A still more delicate test of the reaction of the milk of the entire herd was made by Dr. Austin Peters, of Boston. Hay and grain, as previously stated, were given without beets to two-thirds of the herd, and ten pounds of beets for each cow continued to be fed to the remaining third. The milk of the whole herd was then mixed together in one vat, was tested in the vat, was then quickly transported to the laboratory, a distance of twelve miles, and again tested. The results of these experiments were as follows: The milk from the cows which has been fed with beets was tested directly in the pails at a temperature of 93° F.

Blue litmus paper gave no change whatever.

Red litmus paper was turned slightly blue.

Cochineal and ammonia paper turned still bluer.

The next experiment was made directly from the vat, which, as I have already stated, contained the mixed milk of the whole herd. The temperature was 42° F.

Blue litmus paper showed no change.

Red litmus paper was turned slightly blue.

Cochineal and ammonia paper was turned still bluer.

The same milk was then carried twelve miles, and on being examined in the laboratory with cochineal and ammonia paper turned the paper just as blue as when the milk was tested at the farm. This second experiment is of great interest as showing that the product of the cow can not only be made to correspond to that of human beings, by means of perfectly natural feeding and under perfectly normal conditions, but that this alkaline modification can be produced to such a degree that one-third of the milk is sufficient to destroy by its alkalinity the acidity of the remaining two-thirds.

The next experiment is a question of bacteriology, and is also of considerable importance in the practical use of cow's milk as a food. It has already been found by certain observers that the first portions of milk drawn from the human breast may contain bacteria, while the later part of the milk is sterile. Acting on Mr. Gordon's suggestion, Dr. Austin Peters made the following experiments at the Walker-Gordon barns to determine whether like conditions existed in the milking of cows. Dr. Peters was dressed in a freshly-boiled white suit and cap, and had his hands and arms thoroughly washed with a 1:1000 bichloride of mercury solution. The cow's udder, teats, flanks, sides, groins and abdomen were also washed with the same solution and dried with a freshly-boiled cloth. The milking was then done by Dr. Peters into sterile bottles with the following results:

Of the four cows milked for this experiment, selected without special reference, the bottle No. 1 in each of the following tables represents the first portion of the milk drawn by the hand of the milker directly into the sterile bottles. No. 2 in each table represents milk drawn through a sterile canula directly into the bottle, while Nos. 3 and 4 respectively in each table represent milk drawn by hand after more than one-half of the udder had been emptied. A bacteriological examination of the milk in these bottles by Dr. A. K. Stone, gave the following results:

Bottle.	Colonies.	Colonies.	Colonies.	Colonies.
1	141	157	19	53
2	0	0	1	2
3	0	6	0	0
4	0	0	1	2

To summarize the above, we find that the direct milking of the first half performed by sterile hand shows a milk with a comparatively large number of micrococci and fine bacilli of the same general appearance respectively. We find further, that the milk drawn through the sterile canula was practically sterile, and the milk drawn in the second half of the milking by hand was so uniformly sterile as to awaken the suspicion that the isolated colonies might have been the result of the manipulation between the "cow and the plate."

These experiments at once provided us with a means of producing a milk practically sterile but not sterilized. This experiment also seems to prove that the bacteria which are found in cow's milk do not necessarily come from external sources, whether they be of the cow herself or her surroundings, but that they may also come from some part of the milk tract between the udder and the end of the teat. These conclusions, it may be said, are made with reference to healthy cows.

ANALYSIS OF THE MINERAL MATTER OF HUMAN MILK.

Up to the present time, although a certain number of analyses of the mineral matter of human milk have been made, yet the results for various reasons have been deemed unsatisfactory. Such large quantities of milk are needed for a satisfactory determination of the percentages of each element which make up the total amount, that this in itself has been an important reason for failure in accuracy. The mineral matter of cow's milk on the contrary has not met with the same difficulty in its determination, and has been presented to us in its elemental percentages in a reliable form. As it has always been known that a radical difference exists between these elemental percentages in cow's and in woman's milk, the knowledge of the exact percentages which exist in the latter has lately become of still greater importance, since such decided advantages have been made in the modification of the other elements of cow's milk.

With the view of making some advance in this difficult question and providing for the milk modifiers of the future, a more exact basis for perfecting a substitute food resembling as closely as possible the product of the human breast, I undertook, in the spring of 1893, to procure an unusual and sufficient quantity of human milk for analytical purposes. In the course of a few weeks, by means of the concerted action of numerous assistants, notably that of Dr. Stickney, I collected five and a half litres, which is an unusually large quantity for experimental purposes. This milk was immediately reduced to its mineral constituents in the laboratory of Dr. Charles Harrington. The analysis of this large amount of mineral matter was then jointly made by Dr. Charles Harrington and Dr. L. T. Kinnicutt with the following result:

Unconsumed carbon		0.71
Calcium phosphate	$Ca_3P_2O_8$	23.43
Calcium silicate	$CaSiO_3$	1.35
Calcium oxide	CaO	2.54
Magnesium oxide	MgO	0.96
Iron oxide	Fe_2O_3	0.40
Alumina	Al_2O_3	

I make no report on the potassium and sodium salts, as their analysis was not considered satisfactory and is being made over again.

In comparing the previous analyses which have been published and which can be found in König's Nahrungsmittel, II., 2. Auflage, with this new analysis, we must remember that the previous analyses were made some years ago. In the last few years the processes which are employed have been so much more exact that the results must be considered far more trustworthy than those made at an early date. It is not remarkable, therefore, that decided differences should be found between this new analysis and those which have hitherto been made and presumably this last analysis is the correct one. It has been made with the most absolute care and by means of the most improved technique, by two eminently competent and well-known chemists, who in their work have acted as controls on each other. In this way great precision has been attained.

The chief differences between this new analysis and all previous ones are as follows:

1. The phosphoric acid is less than half as much as previously reported.
2. The magnesia is also less than half as much.
3. Silica and alumina are present; they have not been returned in any previous analysis.

Assuming the truth of the statement that the constituents of the mineral elements of human milk are subject to great fluctuation according to individuality and other causes inherent to the human race, it is right to presume that the mineral matter examined by Kinnicutt and Harrington, being the product of a large number of women, is a fair average specimen.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

STRYCHNINE SUBCUTANEOUSLY IN PERIPHERAL POLYNEURITIS.

Dr. A. Stodart-Walker (*La Semaine Medicale*, No. 1, 1895) in three cases of peripheral polyneuritis obtained excellent results with hypodermic injections of strychnine. One of them was a confirmed drunkard; the second had had rheumatism and was a drinker, while the antecedents of the third were negative. All three were incapable of getting about and were forced to keep their beds; they experienced pain both spontaneously and upon pressure at points corresponding to the affected nerves. Several groups of muscles showed undoubted signs of atrophy; there were anesthetic plaques and the knee-jerk was absent in the first two, increased in the third patient. In these three cases the salicylate of soda, salol, the iodide of potash and salicylic acid had been given in vain, when hypodermics of strychnine caused an almost instantaneous amelioration which progressed to recovery, with complete restoration of motion and sensation. The remedy was injected three times a day, in an initial dose of a half milligram and gradually carried up to two milligrams at an injection.

THYROID FEEDING IN OBESITY.

Drs. Leichtenstern and Wendelstadt (*La Semaine Médicale*, No.1, 1895) of the Augusta Hospital of Cologne, Germany, observing the rapid decrease of weight in patients with myxœdema under treatment by extract of thyroid glands of sheep tried it in simple obesity. In 22 patients out of 25 they obtained a rapid decrease in weight which they attributed to a more active combustion of fat in the organism than to the diuresis which is noticed regularly when the patients first are put upon this treatment. This diminution is

* In charge of the translator, F. H. Pritchard, M.D.

especially rapid at first and gradually becomes less and less. It varies, according to the observations of German physicians, between one to five kilograms the first week and from one and a half to nine kilograms in several weeks of treatment. The remedy may be either employed alone or in connection with a special dietary.

[Dr. Yorke-Davis (*La Semaine Medicale*, Annexes p. clxx., 1894) has already reported satisfactory results with this remedy, in the treatment of obesity.—*Trans.*]

STRYCHNINE IN SNAKE AND SPIDER BITES.

Dr. Mazhar Hossain (*Indian Medical Record*, No. 6, 1894) was called to a Hindu woman of twenty-two years who had been bitten on the big toe by a brownish white cobra, four feet long and three inches in circumference. Her companions saw the snake glide away after having bitten her. An hour after she felt giddy, became insensible and salivated profusely. She was brought three miles into the city to her home. One dram of liquor strychniæ (grs. iv. to an ounce of water) was given in four ounces of water and administered in four doses by the mouth with intervals of fifteen to thirty minutes. After the first two doses she became conscious and continued so all that night and the next day. The day following all the symptoms reappeared; she was salivated, her whole body excepting her corneæ was insensitive, her pulse weak and thready, respiration shallow and about three a minute, and every two or three minutes she convulsed. Deglutition was impossible; the bitten foot was slightly swollen, the marks of the serpent's teeth being distinctly visible. Two injections of twenty drops each were made subcutaneously; in six hours no improvement, except that her pulse was strong and full; the injection of twenty drops was repeated. In ten minutes she came to but could not speak. Injection repeated again in fifteen minutes. Three hours after she was conscious but could not speak; the injection repeated and fifteen drops left to be taken by the mouth. The next day she was improving but still speechless; twenty drops of the liquor strychniæ every three hours. At two o'clock of the third day she regained the use of her voice and all the symptoms then disappeared except a feeling of dull pain over her whole body. Twenty drops of the remedy were ordered three times a day by the mouth for four days, and she soon recovered completely.

A correspondent of the same journal reports a case of bite from a venomous spider which was successfully treated by injection of $\frac{1}{15}$ gr. tablet of strychnia. He was bitten on the penis by a black spider with a red back. Three hours after he was in great pain and almost fainting. He complained that he was loosing the use of his legs; his pulse was rapid, 112, and he was very nervous and much frightened. Immediately after this he fainted and became very drowsy, but in ten minutes he brightened up and became quite calm, the pulse returning to the normal state. The injection had a very marked effect, for though still in great pain he improved from hour to hour and the next day felt well.

DEATH FROM INUNCTION OF MERCURIAL SALVE.

Dr. Sackur (*Memorabilien*, No. 7, 1894) reports the case of a girl of twenty years who after local application of a mercurial salve to numerous "cracks," rhagades, on her hands was soon seized with nausea, vomiting of greenish matter and fainting and she appeared as if very ill. The vomiting continued every quarter of an hour, with tenesmus and slight albuminuria while the temperature was normal. The left arm was of a grayish white and glistening appearance with moderate swelling, yet without fluctuation. Deep incisions upon the volar and dorsal surfaces exposed grayish, dirty and gangrenous subcutaneous and muscular tissue. Though there was no enlarged spleen and the temperature was normal a gangrenous phlegmon, with sepsis was diagnosticated. The next day anuria was noticed and several bloody stools were passed, with colic. The temperature became subnormal, the bloody passages increased in frequency and were of nearly pure blood; violent hematemesis set in and small ulcers formed on the margins of the tongue. The symptoms ag-

gravated and death took place on the fifth day. In all about five grams (ʒj ¼) of the salve were rubbed into her hands but the anemia of the patient undoubtedly aided the poisoning.

AMENORRHŒA.

In *L'Union Medicale du Canada*, No. 10, 1894, in amenorrhœa the following pill is warmly spoken of:

Mercury, bichlorid.....	gr. ¼
Arseniate soda.....	gr. j
Exsiccated sulph. iron....	gr. xxx
Carbon. potash.....	gr. xv
Extr. Nuc Vom.....	gr. v

Sufficient for thirty pills. One before each meal.

LEMONADE FOR DIABETIC PATIENTS.

In the *Journal Des Practiciens*, No. 5, 1894, the following lemonade is suggested for diabetics who suffer from thirst and who beg for a drink, with a sweet taste:

Citric acid.....	5	o	grs lxxvij
Pure glycerine.....	20-30	o	ʒv-ʒj
Pure water.....	1000	o	ʒxxxj. ʒij

To be drunk in small quantities during the twenty-four hours.

BORIC ACID IN CONJUNCTIVITIS.

In the *Medical Chronicle*, No. 6, 1894, the following prescription is recommended in conjunctivitis:

Boric acid.....	grs iv
Borax.....	" xij
Destilled water.....	ʒj

To be used as a collyrium.

POISONING FROM A BELLADONA PLASTER.

Dr. F. J. Clendinnen (*The Australian Medical Journal*, No. 9, 1894) was consulted by a man thirty-five years of age who complained of lumbar pains, was ordered to apply a belladonna plaster of eight by ten inches to his spine. In four days the pains had gone, but he still kept the plaster on. Six days after this he awoke in the morning feeling thirsty and giddy, had no appetite, and on trying to read found that his sight was dim. He attempted to do some business but found that he talked nonsense and was brought home. When seen at 6 P.M. he was delirious and almost unconscious, skin very dry, tongue coated and dry, pupils somewhat dilated and inactive. He had hallucinations of sight and saw ants crawling over his bedstead. He said that he had a hydatid in his brain and wanted to be operated on. He was restless and was continually making imaginary cigarettes and smoking them. The belladonna plaster was still on; it was removed and the skin cleaned thoroughly. His condition rapidly improved and he was practically well twenty-four hours afterward.

ERGOT AS AN OXYTOCIC.

Professor J. G. Swayne (*British Medico-Chirurgical Journal*, No. 9, 1894) thinks ergot to be indicated in long and lingering labors where there is an absence of uterine contractions and consequent lack of dilatation of the parturient canal. This is contrary to the general obstetric views of to-day yet he has confirmed it in a recent case of a young woman of twenty-five who had borne three children and had to do a great deal with deficient uterine contractions during her labors. At the one that the writer attended the waters broke early in the morning and no pains followed; the head of the child could be felt above the os pubis through the anterior lip to be in the ordinary position yet the cervix was soft and cushiony; no "show" and no signs of impending labor. This condition of matters continued for two days, unchanged, when the mother noticed that the fetal movements were no longer to be felt for several hours. The heart sounds and placental murmur were faint though scarcely audible. The liquor amnii which still flowed away at times was found stained with meconium. The cervix was still undilated and no pains appeared. He administered twenty drops of the (American) fluid extract of ergot which he prefers to that of the English pharmacopœa. In twenty minutes from the time of its administration he noticed a distinct uterine contraction; the same dose was repeated in half an hour and again given after half an hour. In three hours and a half from the first giving the drug she had strong and regular pains, the cervix was well dilated; a drachm was then administered and after half a dozen strong pains she gave birth to a fine boy. At first it made no respiratory effort though the umbilical arteries pulsated feebly; he kept up continuous pressure on the uterus until the placenta was expelled during which time the cord was not tied. Artificial respiration, etc., restored the child after half an

hour of effort. Then everything went on well with both mother and child. He admits having transgressed the rule, but with multiparæ with a soft and dilatable os and no pains the state is different from delayed labor in primiparæ from a rigid os; here ergot would do serious injury.

COCAINE IN VOMITING IN PREGNANCY.

Dr. A. Naylor (*The Australasian Medical Gazette*, No. 8, 1894) is an enthusiastic advocate of local application of a solution of cocaine to the cervix, in the vomiting of pregnancy. He tried it with success in one case. He had tried all measures without any great benefit and she had become emaciated to such an extent that life was a burden. A Sim's speculum was introduced, the vaginal roof and cervix were painted with a 15 per cent. solution of cocaine and probe wrapped with cotton and soaked with the solution was introduced into the cervical canal to the extent of about three-quarters of an inch, but with great care. Vomiting ceased with the first application, but nausea still remained. After five daily applications she felt much better, gained flesh and soon looked remarkably well. He thinks that this measure should be tried before abortion or premature labor is attempted as a relief.

INTERSTITIAL INJECTIONS OF CARBOLIC ACID IN FACIAL CARBUNCLE.

Dr. Altmann (*Ibidem*) reports the case of a young man of seventeen years who was affected with a malignant carbuncle of the left side of the lower lip, with submaxillary glandular enlargement, pronounced general symptoms, as high fever, extreme pain, restlessness, a coated tongue, no appetite and slightly albuminous urine. Under local applications of a bichloride solution and poultices he grew worse. Four days after he was seen interstitial injections of a 5 per cent. solution of carbolic acid (ʒjss in all) were made into different parts of the tumor. The local and general symptoms had, the following morning, greatly ameliorated; the injections were continued for two days with decided improvement, and in six days from the first injection he returned to work.

[Dr. Graff, of Christiania, Norway, recommends interstitial injections of pure carbolic acid into carbuncles and indurated boils of the back of the neck. He has injected as much as two hypodermic syringefuls in twenty-four hours into the malignant facial carbuncle of an old woman without noticing the slightest symptoms of poisoning by the drug. He thinks it the remedy par excellence in carbuncles, as the relief of pain and local as well as general symptoms is so immediate and striking.—*Trans.*]

LOCAL APPLICATION IN ECZEMA.

L'Union Medicale Du Canada, No. 10, 1894, recommends in eczema the following local application:

Oil sweet almonds } Glycerine }	.....	āā ʒiij
Oxide Zinc	.....	ʒjss

The *Covremennaya Klinika*, No. 10, 1894, speaks highly in the treatment of emphysema of the lungs, of the following pill:

Arseniate soda	o ss	gr 1-32	
Iodide potash	o ss	" j	
Powdered rhubarb	o ss	" j	
Extr dulcamara q s			

Sufficient for one pill.

For the first few days one pill a day, after which one may increase the dose to two a day.

IODIDE OF POTASH IN CROUPOUS PNEUMONIA.

Dr. Werner (*Memorabilien Hft.* 7, 1894) holds that the iodide of potash is a specific remedy in the early stages of croupous pneumonia of adults, for, if administered within the first twenty-four hours, it may act so as to abort the disease. He has tried it in eleven cases under these conditions and is satisfied with the results. Dr. Mueller, of the Posen military hospital warmly praises its serviceability in the early stages of the disease, which he has confirmed in many cases.

EFFECT OF VACCINATION UPON WHOOPING COUGH.

Dr. Bolognini (*La Semaine Medicale*, No. 1, 1895) has vacinnated thirteen children affected with whooping cough as was recently suggested by other Italian writers as a means of treating whooping cough.

These observations have shown if done at the beginning during the first or at the beginning of the second stage of the disease it will decrease the number of the coughing attacks and diminish the intensity of the affection. Its favorable action will begin to be noticed in one or two weeks. Occasionally, it is preceded by a transitory aggravation of the symptoms. Naturally, where there is no development of pustules from a spontaneous or acquired immunity inoculation will be ineffectual. Therefore, if a child has whooping cough and has not been vaccinated this measure may be done for it will not exert any deleterious influence upon other remedial or hygienic measures.

SALVE FOR ACNE ROSACEA.

In the Russian journal (*Covremennaya Klinika*, No. 10, 1894) in the treatment of acne rosacea, the following salve is praised:

Ichthyol	2 parts
Resorcine	1 "
Collodion	30 "

Apply locally.

CHRONIC INVERSION OF THE UTERUS TREATED BY ELASTIC PRESSURE.

Dr. Christopher Martin (*The Birmingham Medical Review*, No. 10, 1894) recently observed a young woman who four months after delivery presented a chronic involution of the uterus with persistent flooding which had rendered her very anemic, though, still she was able to be about. All attempts at manual reduction of the firm, hard, small and pear-shaped uterus were unavailing, even under chloroform, so he tried continuous pressure by Tait's cup and stem repositor, applying a medium sized cup to the fundus and by means of elastic cords attached above to a waist belt and below to the stem he was able to exert gentle but continuous upward pressure on the fundus in the line of the axis of the pelvic brim. At the end of eighteen hours the cup had returned the cervical portion and only the fundus remained inverted. He then removed the cup and was able by firm upward pressure on the fundus by two fingers in the cervical canal, to effect complete and final reposition. He then washed out the cavity of the flaccid uterus with hot iodine water, administered ergot freely and thus got the uterus to contract. After this the patient recovered without a bad symptom, and she was sent home, at the end of two weeks. Since then she has menstruated regularly and normally and is now in excellent health. The continuous pressure of the repositor gave her considerable pain which required the free administration of morphia during the reduction. He regards manual taxis as useless in the reduction of chronic inversion and believes in the serviceability of continuous elastic pressure. With but a superficial examination in such cases the inverted uterus might have been mistaken for a uterine polypus and an ecraseur applied, with disastrous results. The history of the case and absence of the uterus above the vagina were, however, quite diagnostic.

THE GLYCEROPHOSPHATES IN THERAPEUTICS.

Dr. A. Robin (*Nouveaux Remedes* x. 9, p. 203, 1894) recommends hypodermic injections of glycerophosphates of lime subcutaneously in states of nervous depression, for these salts act fully as well as Brown-Séquard's preparations of testicular juice which contains an uncontrollable quantity of the same drugs. The daily dose is 0.25 gm. (grs. iv). He claims to have obtained good results with them in neurasthenias of various origin, albuminuria, phosphaturia; to have caused a decided increase in weight in Addison's disease and favorable results in sciatica and trigeminal neuralgia. In tabes the results were uncertain beyond an amelioration of the lightning-like pains.

ELECTRICITY IN AMENORRHŒA.

Dr. Doeblin (*Archives d'Electricite Medicale*, No.24, 1894) reports on twenty-three cases of amenorrhœa treated by the faradic current. Fifteen of these were completely cured while four others remained in the same general condition which had brought on their menstrual disturbances. Three women after considerable amelioration were lost from sight and in only one case of amenorrhœa, complicated with obesity was the result absolutely negative. He gives no precise indications as to the intensity of the current nor the number of applications.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

EDITORIAL.

AN OVERCROWDED PROFESSION.

It is not gratifying to professional vanity to be compelled to admit that medical services are subject to the same law of demand and supply which obtains with any other commodity. We may fancy that unbusiness-like methods of collecting and unlimited credit extended to every stranger, are evidences of a charitable spirit and of the inherent differences between the proper conduct of a business and a profession. In many other ways we may seek to explain certain peculiarities in the relation of doctor and patient which do not exist in the case of lawyer and client, nor in that of salesman and patron, yet, after all, there is but one explanation, the overcrowded state of the profession, in which each competing doctor jostles his fellows for the sake of getting patients—as a vague possibility, patients that will pay large fees; by preference, patients that will pay something; but, if a last resort, any kind of suffering humanity that may serve as clinical material.

It seems harsh to rate professional service as a commodity. Such is not the ideal conception. It is rank heresy according to the articles of codal faith. But professional orthodoxy, like the wind, bloweth where it listeth; we hear the sound thereof, but cannot tell whence it comes nor whither it goes. Habitual practice, however, is cognizable by senses other than the hearing—too often the combined evidence results in convicting the sound-sense of falsely impersonating "sound sense." Under existing conditions it is not too much to characterize as commodities, professional services of which one may obtain, by mail, a descriptive catalogue, together with a price-list—usually suggesting liberal discounts; services for which one may go shopping and make the rounds in search of a bargain. A common experience of well-known practitioners, and especially of metropolitan surgeons, is to meet in their consulting rooms some person coming directly from the office of an-

other physician, who inquires the price of some specified service; objects that "even Dr. Blank charges only so much" (always a less amount), and names other doctors who are yet cheaper; asks if the fee named is the lowest; remarks that the matter will be considered and a decision made, and leaves the office to visit the practitioner next on the list. To assent to such a condition of affairs is to enter into competition. And the methods usually taken to persuade possible patients of the superior character of the services offered, may be not inaptly termed "jostling." Undoubtedly the jostling is done in an extremely ethical and courteous manner, and of the two skeletons in the doctor's closet, the reminder of his osteological studies is the less carefully concealed.

Consider our prominent surgeons—and the same is true to a less degree of other clinicians: the work from which they gain skill and upon which they establish reputations is done in the free clinics; the surgery by which they live, is small in proportion. One can go through our cities and find not one physician's residence which would be remarked upon by a stranger. In a neighboring city, of the twenty or more doctors' houses betokening that fortune has been liberal though not lavish in her gifts, all but two have been acquired through inheritance or marriage. Of these two, one is the home of an old bachelor whose long years of economy have gained him the name of being penurious, while in the other is sunk the entire salary of an unexpected term of political office.

The world owes every man a living, if he will work for it. It owes as much to the man who fits himself for a profession and performs faithfully the arduous duties of a physician, as to the one who sells needles and thread, or who juggles with real estate. The physician has a right to expect a living such as will place him on a par with his natural associates, while the laity have a corresponding right to demand that no one shall become a physician who is not worthy to mingle with the substantial and intellectual part of the community.

The average man, making an investment of three years of time and, let us say, five hundred dollars in addition to his actual expenses, ought to be practically assured of a comfortable income at the expiration of the three years. Here is the brief history of one who used the same logic with regard to medical practice. A young man of good education, fair ability and excellent habits, after a thorough course in medicine, decides upon a location, and having a small income, marries. His wife is a woman of good birth and breeding, of splendid education, of natural good sense and willing to help her husband in all the little ways by which a doctor's wife can add to his list of friends and possible patients. In spite of fair prospects, he fails to make a living, though assisted by the influence and to some extent, by the money of relatives. The wife while pregnant, over works; partly from the lack of needed care before and after confinement, she develops pyæmia and dies. Some blame is, naturally, attached to the husband; in addition to his bereavement, he is obliged to begin life anew in a strange place, with added burdens and without the stimulus of youthful hope and ambition. Such dramatic tragedies are rare, but the lives of thousands of physicians are cursed with the unromantic, every-day poverty that may not claim the sympathy of the world, but that is none the less hard to bear.

If the evil of an underpaid medical profession went no further than the requirement of self-denial on the part of the physicians and their immediate families, we should regard it with equanimity as the common lot of a certain proportion of all mankind. But a poorly paid pro-

fession means a poorly treated public. Chemicals, drugs, instruments, books, the time and freedom from financial worries necessary for the thorough study of cases and the acquisition of new knowledge, not to mention in detail the routine expenses of keeping an office—all these cost as much as the entire living expenses of families of moderate means. The public fails to realize that a physician with a gross income of two or three thousand a year, is no better off than a clerk on a salary of one or two thousand, and, on the whole, the medical profession does not care to have the fact made too patent.

It is self-evident that with two men doing one man's work, each will receive not more than half of one man's wages. As a matter of fact, the urgency of competition will compel each to accept a little less than half. The American profession, in proportion to the total population, outnumbers the European profession four to one. Considering, however, the greater diffusion of wealth in this country, it is a conservative statement that the average American physician could double his list of patients without adding materially to his fatigue; indeed with the conveniences which a doubled income would afford, the actual labor might even be diminished. Conversely, with better opportunities for experience and with a better armamentarium, the physician's services would be of greater benefit to the community at large.

We doubt if there will be much controversy over the opinion that the medical profession is seriously overcrowded.

SOCIETY REPORTS.

ALLEGHENY COUNTY MEDICAL SOCIETY.

December 18, 1894.

Dr. J. Chris Lange opened the discussion of the subject announced for the evening, entitled

APPENDICITIS.

(See page 226.)

DISCUSSION.

DR. ADOLPH KŒNIG: I think that a paper of such great interest and importance as the one which has just been read, should receive a thorough discussion. I myself feel thoroughly in accord with what the reader of the paper has said regarding the etiology and treatment of appendicitis, and I cannot understand how surgeons in their text-books will insist that medical treatment of appendicitis is worthless and should not be made use of except at the very beginning, and to a very limited extent. My experience with this disease is limited to perhaps fifteen or twenty cases. In every case in which the disease came under treatment within two or three days after its beginning a favorable result was obtained. I have within the last eighteen months seen two cases in which suppuration took place, but both of these cases had been under treatment by homœopaths for typhoid fever for about a week, until a condition of suppuration existed. Of course they did not get the proper treatment, such as spoken of by Dr. Lange. I have no doubt whatever that if the system is saturated with mercury to a sufficient extent, that the life and activity of the bacillus to which this suppuration is without doubt due, is cut short and its pathogenic action prevented.

DR. J. D. THOMAS: I think the paper a most interesting one. The doctor has spoken of the separation of those cases requiring surgical procedure from those not requiring operation. With regard to the treatment of these cases, of course there is no criticism to be indulged in because the doctor don't exclude operative measures, but the subject of medical treatment might be criticised somewhat. I can say that I have seen quite a number of cases of appendicitis, some of which were operated upon, and others were not operated upon. None of these cases were medically treated, as suggested by the author of this paper; that is, they were not treated with the mild chloride of mercury and morphine. At one time I had three cases on hand, one of which died. The cause of death was rather an unusual one for this disease. It was a clear case of appendicitis, but after three or four days the pain disappeared from the region of the caput and passed around to the region near the spine. The pain over the appendix disappeared entirely. The pain in the back only lasted a day or two, and after that the pain was ascribed to the liver—over the left lobe of the liver. I expect in this case, instead of suppuration taking place about the appendix, that the lymphatics carried some of the poison up into the liver, and I was having a case of abscess of liver. The man died and I secured the privilege of an autopsy. There was no peritonitis. There had been a perforation of the appendix at its point, and the point had become adherent to the peritoneum. The abscess traveled up behind the peritoneum; there was pus between the diaphragm and the liver. The right pleural cavity was full of pus. Now if this case had been operated on in the loin at the commencement of the disease, I am fully satisfied that the patient would have had a fair chance of recovery. This case is not necessarily unique, but it is rather out of the common. It is a very difficult matter to know which cases to operate upon and which to treat medicinally.

About six months ago a case was sent into the South Side Hospital. The temperature was about 100° F. There was very little pain over the region of the appendix, but there was a distinct tumor. The patient came into the hospital in the evening for operation. It was really a case in which I would hardly think it necessary to operate; but the man was all ready for the operation, came prepared for it, and if we did not operate he might think that he was not getting the proper treatment; the treatment he expected. The next day I operated. The man walked into the room, jumped upon the table and certainly did not seem to be a very sick man. I removed the appendix, which I found to be perforated, and there was also evidence of pus formation. It was a case for operation. The patient recovered.

I think the great majority of the cases would get well under proper treatment and without operation. The great questions for me to decide are: What cases require operation and what cases do not? Of course if there is an abscess discoverable an operation is indicated.

I will recite another case. The patient came to my office with all the symptoms of appendicitis. He had been treated by an irregular for colic. The patient was walking about the street. I had him lie upon my table, and upon examination I found an induration as large as a saucer—a large saucer—in the region of the appendix. I sent him home to bed and kept him quiet. From day to day the induration diminished in size and the patient recovered.

DR. R. W. STEWART: I think the paper a very valuable one, in that it treats so fully of the etiology of appendicitis. It also shows us the rudimentary character of appendix and its lowered vitality from lack of function and scantiness of its blood supply. Thus far, there are no points for us to discuss or upon which to differ. The doctor has stolen the thunder of the surgeon by stating that an abscess of the appendix is beyond the reach of medi cine, and that in cases of doubt as to the presence of pus it is advisable to operate. I will concede with the doctor the perniciousness of the rule that an appendix once inflamed should always be removed. I think a rigid adherence to that rule would work a great deal of harm. But I must also express my opinion that his views regarding the efficacy of medical treatment are a little extreme. I think his results are unique considering the methods of treatment.

I also doubt the philosophy or logic of some of his arguments. For instance, his

statement of the power of calomel as an antiseptic. I question very much whether calomel has the efficacy which he ascribes to it as an antiseptic. I question, for instance, his reasoning upon the point of syphilis. He claims the results come from its antiseptic properities. Then how does he account for the many years necessary for treatment? And for the fact that large doses are often less efficacious than small doses? I question also its antiseptic action upon the appendix, because the inflamed appendix is shut off from the general alimentary tract and the local application of an antiseptic is impossible. I therefore fail to see how, with his calomel, he can hope to reach the bacillus coli communis in such a situation. I also question the action of morphine in arresting the function and quieting the parts. The doctor has stated that the appendix has an extremely low vitality, a very scant blood supply and that it is almost devoid of muscular fibers and possesses no function, therefore the administration of morphine can have little effect upon the appendix itself.

Dr. Mark A. Rodgers: I would like to ask Dr. Lange whether he considers the bacillus coli communis a pyogenic micro-organism, or if he is of the opinion that it merely prepares the tissues for invasion by the streptococci and staphylococci of pus formation by lowering the resisting powers of the tissues. If he takes the latter view I think that he differs from almost every modern bacteriologist.

I take exception also to the analogy which he draws between the process of tuberculosis and inflammation, and in this he is also somewhat at variance with most modern pathologists; for, according to the best modern authorities, tuberculosis, with syphilis, leprosy, etc., are classed with the specific granulomata and are not inflammatory processes. I therefore fail to see the analogy which the doctor points out.

Dr. X. O. Werder: I think the paper just read is a very scientific one. There are only a few points upon which I cannot agree with the doctor. The first point is regarding the frequency of the disease in the male over that found in the female. He claims that it occurs in eighty per cent. in the male to twenty per cent. in the female. I think that the disease is just as common in the female as in the male. In the woman many cases are undoubtedly associated with diseases of the ovary or tube. In many cases of abdominal operation I have found a diseased appendix and have frequently come to the conclusion that the diseased appendix was the primary cause of the pelvic trouble.

There is another matter. Dr. Lange says that Dr. Murphy, in his one hundred and forty-five cases, removed the appendix in sixty cases; but failed to remove it in sixty-eight cases. That may all be; I have not seen the statistics. It can be very easily explained. The abscess may be found to exist in the peritoneal cavity, but completely surrounded by adhesions and shut off from the general cavity. In such a case the duty of the surgeon is merely to open and treat the abscess. It is not his duty, and not wise, to hunt for the appendix. All that he should do is to attend to the abscess and let the appendix alone. I think this is the explanation why Dr. Murphy did not remove the appendix in sixty-eight cases.

Another thing that struck me in Dr. Lange's paper, and that was that Dr. Murphy found pus formation in such a large number of cases. I was present at the last meeting of the American Association of Obstetricians and Gynecologists at Toronto, at which Dr. Murphy discussed appendicitis. His advice was to operate early, at once, the same hour if possible, whenever appendicitis was present. The fact that in spite of such early operations pus was found in such a large number of cases shows that pus must be present often in the beginning of the disease.

Dr. Lange cites a case in which everything was ready for operation, but at the last moment such a marked improvement was shown that the operation was postponed. Now what happened in this case? It was undoubtedly an abscess. It could not have dragged along from seventeen to twenty days without pus formation. What happened? The abscess ruptured into the bowels. Improvement followed at once. I have had just such a case. I remember it was on Sunday night that I first saw the patient. I decided on operation and directed the ambulance to call for him Monday. The next day, before the ambulance arrived, I went to see the boy and found a marked improvement.

The nurse showed me a vessel in which I found a good deal of pus. I think many of these cases rupture in this manner. I think Dr. Sonnenburg takes this position, and is correct. In all cases where tumefaction and tumor is shown in the right iliac region, diagnosed as appendicitis, there is pus formation, and frequently these cases do require operation. Many cases do not rupture into the intestines. The liquid portions become absorbed and the residue remains there, perhaps, in the future to cause a new inflammation. In a manner these cases resemble very much the condition we find in the tubes in salpingitis. The time will come when we will remove the appendix in appendicitis just as we do a tube in salpingitis.

Dr. J. M. Batten: I always feel like taking a conservative stand in matters of this kind. If we take into consideration the theories of Dr. Lange, surgeons often operate unnecessarily in very many of these cases; and I think considering the results which he has shown that his paper should receive careful attention.

My experience bears me out in saying that I do not think appendicitis is a very difficult disease to treat; nor a very dangerous one, even if it runs to suppuration. I have had several cases of it. Some of them convalesced without operation; and in others when pus had formed, operations were performed and the patients recovered. I think there are too many operations for appendicitis, and think that if there were fewer operations there would be a greater percentage of recoveries. Dr. Thomas has said that it is very difficult to know just when to operate and when not to operate. Dr. Lange in his paper recommends operations only when we have pus formation. I do not think it a very difficult matter to discover an abscess in a case of appendicitis, provided the case has reached that stage.

Dr. James W. Macfarlane: The gentleman at my right hand (Dr. Batten) does not think it a very difficult thing to tell when there is pus formation in appendicitis. If such were the case there would not be such divergence of opinion as has been shown here to-night. Perhaps Dr. Lange is a little too enthusiastic on the one hand, and my friends, the surgeons, too positive on the other. I think we should be willing to concede, to a certain extent at least, the efficiency of Dr. Lange's treatment. I agree with what Dr. Werder has said regarding the treatment of appendicular abscess and the limitations of the surgeon's duty with regard to the removal of the appendix under such circumstances. This is especially true where you have a good-sized abscess. Surgeons may be a little too ready to operate; but, on the other hand, medical men are often so loath to operate, or to consent to operate, that valuable time is lost.

There is one thing that seems to me should have due consideration in the discussion of this disease; namely, the disposition to have hernia follow an operation for appendicitis. This liability may not be so apparent in the results of certain operators as that of others; still it is liable to occur in the hands of the most expert surgeon. This fact should not deter us from operating, but shows that too great care cannot be taken to avoid this complication.

Dr. C. C. Hersman: A number of years ago I can remember when most cases of this character were treated under the names typhlitis and perityphlitis. To-day the enthusiast calls everything appendicitis. In the few cases which I have had none were operated on. Possibly but one should have been operated on. That case died. The post-mortem revealed a rupture of the appendix and a general peritonitis. I presume if she had been operated on early good results might have been obtained. So far as treatment is concerned, either medical or surgical, I am inclined to think, with some of the gentlemen present, that it is a difficult matter to determine in the earlier stages, whether there is pus formation or not. In some of my cases I could make out no swelling whatever. I had a case of this kind not very long ago upon which I had consultation. My consultant was a very competent gentleman. I had made out no swelling and he found none, but there was great tenderness and pain over the region of the appendix and a pronounced tympanites. There was no operation performed. The patient was treated medically and made a recovery.

So far as the calomel treatment is concerned I have my notions about it. I employ it in combination with morphine. The morphine sets the patient at rest and quiets peristalic action. So far as relieving or controlling the function of the ap-

pendix is concerned I am not able to say that I have ever found any function for the appendix except that of giving its possessor trouble.

I cannot accept the statement that calomel in such small doses acts so powerfully as an antiseptic. I do believe that calomel is one of the greatest therapeutic agents we have in increasing the activity of the glandular system of the alimentary canal. I think this is its action. It increases the activity and fortifies the economy against the ravages of the disease. It helps to carry off the disease, to get rid of it. Another reason why it does not act antiseptically in affections of the appendix is because it does not penetrate. The blood supply of the appendix is of such a limited character that I do not think that the medical agent can possibly act directly within the substance of the appendix. I think instead of an antiseptic action it is by increasing the activity spoken of a moment ago that the drug produces good results and fortifies the glandular system against disease and helps to get rid of it.

Dr. G. M. Shillito: All the cases of appendicitis which have come under my notice have recovered with the exception of one. At the autopsy of the latter case we could find very little evidence of inflammation, almost none at all, of the appendix; but there was a rather extensive peritonitis. The first thing we found upon opening the appendix was a grain of corn cut through in the middle and therefore, in this case at least, there was a "foreign body."

Dr. J. M. Duff: I fortunately can say that of a number of cases of appendicitis which have come under my care (and in a number of the cases my diagnosis was confirmed by others) nearly all recovered. The cases which came early under my care recovered with aid of medical treatment. I recall the case of one patient who died. He did not come under my care until there was pus formation. This case was seen by a couple of gentlemen who are here tonight. This case resembles the one referred to by Dr. Thomas very much indeed. There was an abscess of the liver and a breaking through of pus into the peritoneal and pleural cavities and discharged through the lung. There was formation of pus in the lung. I am willing to admit the efficacy of medical treatment for appendicitis if the case comes under the physician's care in the early stages. I believe that every case of appendicitis should be operated upon. I feel I am justified in taking this ground for many reasons. I say in every case, unless it might be a few cases which come into the hands of experts who have a fine diagnostic ability which is not in the possession of the great majority of medical men. I do not like to be radical—to be extremely radical. I do not wish to take a radical stand upon any subject as a rule, but I will ask you to consider calmly this question in all its bearings.

I don't deny but that Dr. Lange has had excellent success in treating these cases medicinally; and that others without doubt have also had excellent results from medical treatment. Dr. Lange admits that there are certain cases in which the surgeon should operate. He then goes on and states that the appendix possesses a very low order of tissue, and he follows that up by stating that the plastic exudation which becomes organized after an attack of appendicitis is of a still lower order of tissue. This lower order of tissue does not require so great a degree of circulation, but we do have a tissue that is liable to disintegration, to gangrene and to disease from interference with the small degree of circulation which it still possesses; in consequence we are liable to have a recurrence of the disease, although Dr. Lange has endeavored to make this percentage a very small one. There is certainly liability of a recurrence.

There are two points in favor of an immediate operation. In the first place you are not always able to tell whether or not there is pus formation in the earlier stages. The second point is the liability of a recurrence. Then it may rupture and the pus discharge internally, causing peritonitis from which cause the patient may die in a few hours. If you don't operate at once you are running some very grave risks. Arguing on that line it would not be wise to wait until you have positive evidence of pus formation. In the earlier stages operation is practically without danger.

We must most assuredly take into consideration the liability of recurrent attacks. We live in an age of rapid transit. Our friends are no longer confined to a circumscribed locality. We have become a

traveling public; here to-day and there to-morrow. A person who has suffered from appendicitis is never safe away from home and away from a skilled medical attendant who understands his case thoroughly. They don't know what moment they may come down with an attack; an attack that may prove very serious, perhaps culminating in death, if unable to to receive the proper treatment. With the removal of the appendix we may say that the liability of a recurrence is practically abolished. This liability of recurrence must receive attention. In the cases to which I will now make reference two or three of the gentlemen present can verify my statements. I refer to two cases in each of which there had been an attack of appendicitis apparently cured by medication; but in both cases there were recurrent attacks from time to time, and finally both cases were operated upon. A third case was operated upon as suggested by Dr. Werder, for ovarian trouble, and we found that the original trouble was an appendicitis. There had been recurrent attacks in this case also. In the first two cases mentioned, in both of them, there was pus formation. In one, however, there was no more than five drops of pus; but there was plenty to show under a macroscopic examination the presence of pus, and it was so pronounced by the gentlemen present. In the other case there was perhaps a half teaspoonful of pus. With that condition there is always danger. There is also danger of its rupturing within the peritoneal cavity and setting up a severe peritonitis.

Let me repeat: I am inclined to be very radical in the treatment of this disease. My opinions have been formed from conversations with Dr. Murphy and other surgeons of large experience and from my personal observations. I feel that I am perfectly justified in making the assertion that every case of this kind should be operated upon as early as possible.

I may modify my opinion when I have the assurance that we can prevent pus formation positively in the majority of cases, and when we have diagnostic symptoms pointed out to us defining the borderline, so that we can say thus far and no farther can we depend on medical treatment.

DR. J. E. RIGG: I wish to also state that I think it is very difficult to decide when to operate and when not to operate. There is a great difficulty in ascertaining positively if any pus formation exists, especially very deep seated. There may be deaths which result from lack of operation. A case may be occasionally lost in this way. But, on the other hand, there has nothing been said to-night about deaths resulting soon after operation, or of the death of persons who have been operated on at some preceding time. I believe there may be deaths traced to the operation which might have been avoided if treated medicinally. I do not believe that Dr. Lange's cases are so much above the average of cases of other physicians which are treated medicinally, although perhaps not exactly according to his method. I believe his results are about on a par with the general run of cases.

You will all admit that the surgeon finds difficulty, at times, in recognizing tissue, especially diseased tissue. Take a congested, inflamed tissue; cutting through one tissue you are rapidly approaching the contiguous one, and frequently you will cut through an adhesion and into the bowel; sometimes in more than one place, as I have seen. You then have the bowel to attend to, and perhaps other complications will arise and the patient die before he is out of your hands entirely. Now if you take the cases which die as a direct or indirect result of the operation in a given number of cases, and compare with the number whom you may conjecture die from *not* being operated upon, I believe the statistics will be in favor of not operating. Unless there is the most positive proof of pus formation, I do not see the necessity of taking an extreme view of this matter. Of course I believe there are cases which should be operated upon; but their number, in my opinion, is quite limited and calls for the best judgment of the physician or surgeon.

The question brought up by Dr. Macfarlane with reference to the liability of hernia following an operation for appendicitis should receive consideration. I have seen it frequently following this operation and causing no little inconvenience and trouble.

I have a number of cases of appendicitis. One of them, after three attacks, has now had none for twelve years. The

three attacks were all in one year. There was a good deal of tumefaction extending over to near the region of the umbilicus. There was not a very long period of time between the attacks; perhaps three months as I recall it now. When I last saw the patient there had been no trouble for twelve years.

I was called one morning to see a little boy. The case diagnosed as appendicitis and consent of the parents obtained for an operation to be performed that day. He had taken sick the day before. I gave as my opinion that we ought to wait a little time before resorting to such extreme measures. The case was not operated on, and after a short time was well and has remained well since. I think the wiser plan is to wait and watch the progress of the patient a while before deciding upon operation.

Dr. E. B. Borland: I agree with Dr. Lange in his plea for early treatment in this disease before the formation of pus. This is my observation also; but I don't think the diagnosis of abscess is so extremely difficult. There is the characteristic temperature, the characteristic pulse, etc.; and these signs, taken in connection with the local symptoms, point to the formation of abscess. I do not think that pus forms within two or three days from the beginning of the disease. I think the action here is much like abscess in other tissues of similar structure. Possibly they may form a little more rapidly; but abscess in most of the other tissues of the body takes several days at least, oftener one week, and sometimes two or three weeks, to form as in case No. 18 of Dr. Lange. During this period is the time for active medical treatment. Now if these cases are attended promptly and treated as scientifically in the early stages, as other similar inflammations, then there is seldom need for surgical interference. Pus formation is, I think, the only indication for operation.

Dr. Lange's paper refers to the lessened vitality of the appendix after an attack of appendicitis. It seems to me that we often forget the conservatism of nature and the power of nature to organize and build up a tissue wherein there has been no pus formation or where the formation of pus over an extensive area has been prevented.

Dr. W. W. Potter: I think one of the most trying times in the life of a physician is the time when he must determine when to operate in a case of this disease and when to withhold the knife. I would like to agree with Dr. Lange in his treatment. In the great part of it, it is good. I must disagree, however, in the matter of locking up a loaded bowel. I believe this would be decidedly detrimental. A thorough cleaning out in cases that are seen early and then a locking up of the bowel seems to me the better procedure. At this time much can be accomplished by the application of ice externally.

Dr. J. J. Green: I am a little like some of the others here to-night, somewhat inclined to both sides. I have treated a reasonably large number of cases of appendicitis. In the early part of my career, some of these cases were treated under the name of typhilitis, some under the name of perityphlitis, and also under the name of paratyphlitis; we now are inclined to call everything appendicitis. I am not quite willing, at the present time, to say that all the trouble in the region of the right iliac fossa is appendicitis, and I guess the weight of authority is with me. I wish, however, to express my interest in Dr. Lange's very able paper which holds very nearly to my opinion, except in some minor particulars. There may be other obstructions in the intestinal canal which must not be referred to the appendix, although situated in the right iliac fossa, and presenting a well marked sausage-shaped tumor which Dr. Lange has relied upon for his diagnosis mainly. I am not able to state in what per cent. of cases the sausage-shaped tumor can be detected. In Dr. Osler's work, I think it is mentioned as about seventy-five.

I don't believe in postponing operations too long. However, I have postponed operations in a case or two, perhaps three, and afterwards operated when it was too late. I failed in one case to distinguish a tumor or any systemic disturbance at the end of one week which would justify me in pronouncing it a case of pus formation. The case was afterwards operated upon and an abscess was evacuated which contained from four to six ounces of matter. The abscess was very low down in the right iliac fossa.

It is my practice to bind up the bowel very early in the treatment of the disease.

I also agree with Dr. Lange very heartily in the use of calomel in these cases. But I fail to see the ability of the agent to reach the whole alimentary canal and produce such a powerful antiseptic action. Dr. Lange seems to have sailed on a remarkably calm sea Nearly all of the physicians with whom I am familiar have met disaster in both channels. The exact time to operate in all cases is very difficult to determine. I am quite confident that when an operation in appendicitis is demanded we should not place the hour for the operation a minute later than is actually necessary for the preparation of patient and instruments.

DR. LANGE in closing the discussion said: I am obliged to you, gentlemen, for the consideration given my rather positive position. Feeling the truth of my position, I mean my insistance that purgation and enemata can do only evil in appendicitis, I am constrained to be emphatic because this is against all teaching and all text books. When I presented my list of cases here before, my success was called phenomenal; again this evening it has been so classed. If any insinuation of error or misstatement is meant by this term, I bear it with equanimity and assure you it is undeserved. In eleven of the first list of cases published I had associates. I named them. In the serious case reported to-night I have named my associates. There was no doubt about diagnosis.

Dr. Werder explains why Dr. Murphy did not remove the appendix in so many of his cases. No criticism of Dr. Murphy was in my mind and none could be implied in my statements. I have seen many cases of appendix operations and am, like you all, familiar with conditions very common which make removal impossible or bad surgery. I know that when the surgeon has emptied and drained the abscess his whole duty is done. I cited the fact as illustrative of how operation does not insure the future safety of the patient, any more than medical treatment can do this, when the appendix must be left, which was in sixty-eight of Dr. Murphy's operations. The fact that more or less appendix tissues sloughed can be only considered on a par with changes of these tissues when inflamed and medically treated. What these changes are, to what extent they may prevent recurrence, no one can estimate of individual cases nor of aggregates. This applies to both medical cases and surgical cases where the organ must be left—in Dr. Murphy's more than 50 per cent.—68 cases.

Dr. Werder further states that my last case recovered because an abscess emptied into the bowel. Here is the patient's chart: His temperature was 101 8° and steadily at that. There is no temperature below normal. There is no hard pulse. There is no sweat. The tumor was not diminished in size. There is not one sign of pus. The stools were carefully examined. Dr. Werder's assumption is not warranted. On the other hand the quiet of the intestines enforced by a return to the administration of morphine in conjunction with the subgallate of bismuth prevented pus formation at this crisis; and this was appreciated by the surgeons who with me observed it.

Dr. Rodgers objects to my analogy between hip inflammation and appendicitis, and holds tuberculosis as an affection not inflammatory. Tubercle belongs to the new formations. But whenever and wherever it exists in the body it involves an inflammation. The bacillus builds for itself, if I may so express myself, an habitation, the grey nodule of Bayle, composed of leucocytes, lymphoid cells and giant cells which it occupies; and this, undergoing transformation by caseation, *i.e.*, becoming the yellow nodule of Virchow, is destroyed, together with its seat, living tissue, leaving an ulcer, *i.e.*, a solution of continuity surrounded by a zone of inflammation. The bacillus coli communis is non-pathogenic in the healthy intestines, but becomes pathogenic in the appendix when its tissues become sufficiently devitalized to admit penetration of its mucosa.

Dr. Shillito's case where a grain of corn perforated the appendix belongs to that small class of cases which has been admitted and called traumatic, though its penetration itself is evidence of low tissue vitality—it would have happened nowhere else in the intestine.

I recognize as a hopeless task any endeavor to combat the surgical bias of Dr. Duff.

Dr. Potter, and by no means is he alone in his position, thinks it proper to use purgation or saline cathartics in the beginning of the inflammation, to empty

out the bowel. I have tried hard to learn, I have repeatedly asked, what injury can it do to lock up the intestinal tract? What substance offends? How does it offend? What results from its offending? All the answer I can get is the vague and ancient axiom about keeping open the primæ viæ on principle. If, gentlemen, you will do this, if you will but rest the appendix when first inflamed, if you will keep it still and keep still its contiguous intestines which by their peristalsis agitate and press upon it and drag it about, then you will no longer call my results in these cases phenomenal.

It has been objected also that calomel cannot reach the appendix, more especially when peristalsis has been abolished by the accompanying morphine. I reply that calomel reaches everywhere, including the appendix tissues. It makes the teeth fall out, if this is desired. It is constitutional, a general antiseptic as well as local germicide. We may be certain it reaches the appendix tissues through the circulation.

The percentum of cases for males and females which I have given is thought incorrect; Dr. Werder, I think, stating that they are about equal. In answer I refer you again to the work of Dr. Fowler where you will find that analysis of many hundred cases gives one in females for every four in males. This is a matter of importance, inasmuch as it forms the anatomical base upon which the pathology —the first step, the initial lesion, rests. That is to say the better vitality of the appendix tissues in the female because of the better, the additional, blood supply from a vessel in the appendiculoövarian ligament.

RECTAL feeding may be carried on by means of a mixture of two eggs, twenty grains of pepsin, ten grains of chloride of sodium, and six ounces of water. This mixture should be slightly warmed, thoroughly agitated, and then gently introduced into the bowels by means of a syringe. To facilitate the entrance of the fluid into the intestines it is well to put the patient in a position with the hips much elevated above the head, either the knee-chest position or with two or three pillows resting beneath the hips.—*Toledo Medical Compend.*

Chloral Hydrate in Labor.

Chloral hydrate, says Dr. John E. Gardner (*Lancet*) has a great effect in assisting dilatation of the os uteri and relaxing the rigidity of the perineum. No post-partum hemorrhage follows, nor is there any delay or difficulty in the expulsion of the placenta. The chloral, I think, might take the place of chloroform, if given in small repeated doses during the long and tedious labor of the primipara. It does not seem to diminish the expulsive power of the pains, as I have often noticed in chloroform cases. I submit that the chloral might be further tried in place of chloroform in primiparae in order to relieve the rigid perineum and so avoid having to use forceps. Chloroform, in my experience, is attended with a great tendency to post-partum hemorrhage, which I have never seen after the use of chloral in labor. For many years I have from time to time experienced its boon to the poor, worn out and anxious mother, despondent with fear. After a dose of the chloral the frenzy passes off, and the patient settles down to her travail, which has a happy and speedy result.

Malarial Pseudo-Tuberculosis.

Charles Duba (*Brit. Med. Jour.*) describes this condition as not infrequent in malarial countries. It attacks persons who for some considerable period have been affected with ague, and begins with marked weakness, depression, loss of appetite, and emaciation. A dry hacking cough, together with dyspnea and irregular temperature, especially towards night, supervenes. Hemoptysis sometimes occurs. Physical examination of the sputa, however, does not show evidenc of special consolidation. Examination of the sputa, however, does not show the presence of tubercle bacilli. The cases recover under the influence of quinine and arsenic, provided the cachezia be not too advanced. The explanation of this condition, which may so easily be mistaken for tuberculosis, seems to be that a local pneumonic process is started at the apices by an accumulation of pigments in the circulating blood.

THE Monobromate of camphor thoroughly trituated with sugar of milk is a specific in small doses for all disorders of childhood caused by reflex nervous irritation, especially those of detention.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

for December. Beverly Robinson, M.D., Clinical Professor of Medicine at the Bellevue Hospital Medical College, N. Y., contributes a paper entitled

A Contribution to the Treatment of Organic Disease of the Heart.

One of the facts that is most prominent in the author's estimate of organic affections of the heart is that which shows the little need at times, of treating heart disease merely because a murmur is present. If accompanying the murmur there be rational symptoms of cardiac incompetency, such as pain, dyspnœa, palpitations, and if to these be added hypertrophy or dilatation, there can be no question that properly instituted medication may be of great service and relieve all distress for a while. In administering drugs we must recognize, however, that we give them for the purpose of relieving symptoms or diminishing the complicating conditions, not to cure the chronic valvular disease; once the latter is well established it is there to remain, and our effort should be not to cure, but to prevent it from becoming really injurious by reason of its possible effects.

Perfect compensation in chronic disease is what we wish and seek to attain when it is broken. When it is present no treatment is required.

In rheumatism the most common cause of chronic valvular disease, the author's treatment is an alkaline one, sometimes by means of bicarbonate of soda and Rochelle salts in moderate, frequently-repeated doses, sometimes with acetate or potash and chloride of ammonium. Either of these combinations seem to him preferable to the use of salicylates in neutralizing the bad effects of acute rheumatism. He has occasionally been of the opinion that the duration of the disease in its acute form was thus lessened and he is confident that the pain is frequently diminished in a marked degree. In a few cases where the temperature was high, the pulse bounding, he has used the addition of small doses of aconite to the second mixture for a few days with apparent good effects

Rest in bed in acute endocarditis is all important so as to reduce as far as possible cardiac activity. And not only is this confinement to bed essential during the febrile stage of endocarditis, but it should be kept up for many days after this is over, and when the rheumatic pains are no longer very pronounced. Even after the patient sits up particular attention should be paid to him, and so soon as he shows signs of fatigue he must immediately return to bed.

As regards the dietary in chronic valvular disease, we must insist upon what is wholesome, viz., roast and broiled meats, no rich sauces, condiments or made dishes. The ordinary fresh vegetables may be allowed, avoiding as far as possible those that are canned. Potatoes are often injurious, as they produce flatus and are difficult of digestion. Alcohol is bad in anything but a limited amount. It may be given in moderation at meal time to stimulate appetite or promote digestion; more than this will probably occasion gastric catarrh, which is decidedly prejudicial by injuring the powers of digestion. Tobacco should be avoided, as a rule, as it is so apt to render the heart irritable and produce palpitation and cardiac distress Very rarely in the author's experience has it been evidently useful. Tea and coffee are also to be taken in small quantities and not too often. After dinner coffee or tea should not be taken as they often disturb a night's rest, and thus bring on a condition of bodily discomfort which is in no wise compensated for by the temporary exhileration which is felt after their use.

Constipation must be attended to; and even though the bowels move regularly an occasional purgative dose will help relieve the first appearance of congestion of the different internal organs in an effective manner.

Of those remedies which stimulate the heart's action digitalis easily ranks first, and must be given without regard to the nature of the lesion whenever the heart begins to fail and is unrelieved by hygienic measures. Strychnia may be combined with the digitalis and, if there be any chronic lung affection as cirrhosis or emphysema, carbonate of ammonia. As a rule digitalis should be intermitted from time to time in order to obtain the best results. While the author does not believe in the idea that digitalis may lie dormant in the system to suddenly become active and produce poisoning, yet if its bad effects are once produced it is often difficult to again obtain tolerance of the drug. In the latter stages of mitral regurgitation when dropsy has set in, the action of digitalis is less satisfactory on account of the contraction of the arterioles produced, because this effect militates against its diuretic action. In order to obviate as far as possible this untoward action of digitalis, it should be given concomitantly with moderate doses of nitroglycerin. The author's plan is to give one dram of the infusion of digitalis and $\frac{1}{200}$ grain of nitro-glycerin every two hours, and progressively increase both of them if need be up to two or three drams of the infusion of digitalis every two hours, and $\frac{1}{50}$ grain or even more of the nitro-glycerin at similar intervals. If the digitalis apparently causes nausea or vomiting, if the pulse under its influence, instead of becoming stronger and more regular, becomes weaker, intermittent, and very slow, it is time to diminish or it may interrupt its use for several hours or

days. These indications are even more formal whenever the quantity of urine remains the same and its density is unaltered. As regards the nitro-glycerin, if the head throbs and pains in a notable manner, whilst the pulse remains small, feeble and uncertain, to increase its dose would be to question utility. The author prefers a freshly prepared solution of nitro-glycerin to the tablets which he thinks are often unreliable.

The author regards the action of the hydragogue purgatives as very important in relieving dropsy, and particularly in those cases where digitalis in moderate doses and by itself has not notably increased the bulk of the urine. Compound jalap powder, with or without calomel, is the preparation which he considers the most reliable among the purgatives, while elaterium and croton oil are not desirable if they can be avoided, or if the compound jalap or scammony powders prove active and beneficial. In these instances the author believes that it is important that no solid food should be given and that the diet should be a strictly fluid one and even the amount of fluid be limited. Of course the severity in regard to fluids should only last while the dropsical condition is very threatening. It is especially important whenever the serous cavity contains fluid, either the chest or abdomen, to let it out by paracentesis, or otherwise the patient's chances of even temporary recovery are greatly diminished.

In those cases of incompetency of the tricuspid valves with engorgement of the right heart, we have one other means of relief, namely, blood letting. It will not answer in an advanced state of incompetency to do more than afford relief in this way. If we attempt it we are apt to weaken the patient too much, and the heart soon ceases to contract altogether and stops in diastole. This indication for the relief of the right heart by venesection in acute dilatation is not changed by the fact that there may be old bronchial inflammation with emphysema; on the contrary it is just such cases that this means may be most potent for saving life, and all other means without it appears at times to be insufficient or unavailing.

The author is a firm believer in the efficacy of caffine in heart disease. In his judgment it is especially adapted to certain cases of mitral stenosis in which dyspnœa is excessive and where digitalis does not seem to act well. It is also very desirable to make use of citrate of caffiene in combination with strychnine in cases of aortic incompetence which do not respond favorably to the action of digitalis. Whenever the powers of assimilation are very imperfect, the salicylate or benzoate of caffiene may be employed hypodermically by reason of their perfect solubility and their non-irritant local effects. The author has also used convallaria for many years with good results.

He is opposed to the use of aconite in mitral stenosis and believes that a far better plan of action is to use repeated doses of nitroglycerine in all urgent cases and whenever the patient has been unrelieved by caffiene and convallaria, and afterward to follow up the use of nitroglycerine by the long continued use of strychnine or nux vomica. Even with children, the cases where the author considers the use of aconite of benefit, are rare and unless the child has fever with the intra-cardiac condition, which is apparently of ephemeral nature and without evident localization, he is loath to give aconite except in very small doses.

In certain cases of cardiac hypertrophy with or independent of a valvular lesion, aconite has been given with apparent benefit by some to quiet the throbbing and pulsation in the chest, apparently indicative of excessive heart action. In these cases he prefers the bromides, and regards the bromide of sodium as the least harmful of the group. What is true of the bromides is also true of the valerianates—and valerianate of amonia in pill form the writer regards as a most useful adjunct to our treatment of these cases.

In cardiac hypertrophy, when the tension is diminished by reason of the failure or rupture of one of the coronary cusps, we have tumultuous intra-thoracic throbbings, but they show weakness and not strength and should be treated with heart tonic like strychnia and iron.

Belladonna, the writer thinks, is often forgotten as to its beneficial action whenever neurosal difficulty is present in any condition of heart depression, without regard to the precise organic disease which prevails. In combination with iodide of potassium it certainly gives marked relief in many cases of aortic diseases in which part, at least, of the pain is apparently connected with a lack of synchronous rhythmic contractions between the two sides of the heart, connected with an insufficient or a badly co-ordinated nervous control. Possibly its stimulating effect upon the nervous centers controlling respiration may have also great value in the re-establishment of heart power and more perfect rhythmic action.

Electricity may also be of benefit in certain cases.

William T. Howard, Jr., M.D., Associate Professor of Pathology, Western Reserve University, Cleveland, Ohio, reports "A Case of Acute Ulcerative Endocarditis due to the Bacillus Diphtheriæ" This is the first reported case of endocardial lesion due to the bacillus diphtheriæ, and it is also the first time that this organism has been found associated with lesion of any of the internal organs other than the lungs; and for these reasons it must be regarded as a unique case.

John B. Roberts, A.M., M.D., of Philadelphia, in a paper entitled "Recent Experience with Tumors of the Liver," reports several cases.

M. Allen Starr, M.D., Professor of Nervous Diseases in the College of Physicians and Surgeons, New York, reports a case of Megalocephalic, or Leontiasis Ossea." The paper is illustrated with photographs of the patient in different stages of the disease. The author is of the opinion that the case reported is an instance of this disease, and that we can affirm that in these cases there is not only a hypertrophy of the bony tissue, but also of

the soft parts about it. It is probably that the diffuse thickening of the bones of the head and neck causes some pressure upon the nerves at their exits between the vertebræ and this might explain some of the symptoms which were present in the patient—especially the complaints of numbness and the difficulty in her gait. Various forms of treatment have been pursued in the case under consideration. A thorough trial of thyroid extract failed to affect the condition in any way, and did not cause any variation in temperature from normal. The use of arsenic and iron with strychnine, given in moderate doses, appears to have had some tonic effect, and these, together with the moderate use of corrosive sublimate internally, are the remedies relied upon. The author ventures to give the condition the name megalo-cephalic, because the term leontiasis has been applied to three entirely distinct conditions, and therefore leads to confusion.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY

for November. Dr. Marcus Rosenwasser, of Cleveland, Ohio, contributes an article on

Abdominal Section in Intra-Pelvic Hæmorrhage.

The author advocates vigilant delay at absolute rest in circumscribed hæmorrhage, basing his plea on the fact that there is no immediate danger, and that active surgical interference is proper only for definite indications, or when vigilance and rest are not practicable. "Our ideal is early recognition and early operation—before the loss of blood has proved fatal, before dangerous adhesions have formed, before sepsis has set in, and while the operation is comparatively simple and safe. But when the case has continued for some time unrecognized, when a tumor has formed, and adhesions have become organized, the possibility of absorption is so great that it ought not to be disregarded. The operation, on the other hand, has become proportionately more difficult and dangerous, and ought not to be done except for cause." Appended to the paper is a table of ope cases.

A. H. Cordier, M.D., Lecturer on Abdominal Surgery, Kansas City Medical College, Kansas City, Mo., discusses the subject of

Hydrosalpinx.

The author does not believe that all cases of hydrosalpinx originate as a result of a suppurative disease of the tubes and the mild cases, those presenting few severe symptoms during their long periods of existence, and few adhesive bands and little injury to the ovaries, are cases that probably have their origin in a catarrhal salpingitis or a subinvolution of the tube following a septic "getting up" after a full term labor or a miscarriage. These cases are rarely diagnosed prior to operation, hence the fallacy of any one advising catheterization as a relief or cure.

G. S. Peck, consulting surgeon Youngstown City Hospital, Youngstown, Ohio, presents the "Report of Four Cases of Adpendicitis Surgically Treated in Thirty-seven Consecutive Hours." Out of the four cases there were two deaths.

Hugh H. Hamilton, M.D., of Harrisburg, Pa., describes "A Clamp for the Obstetric Forceps."

The editorial in this month's issue is concerned with Dr. Viquerat's treatment of tuberculosis.

In the Department of Pædiatry there appears a paper by Charles Greene Cumston, M.D., on "The Treatment of Whooping Cough, with Special Reference to Antipyrine." While the author does not regard the drug as a specific in this disease, he believes that it is of very great service in the treatment.

JOURNAL OF NERVOUS AND MENTAL DISEASES.

Dr. Henry R. Stedman writes of the

Management of Convalescence of the Insane.

The patients suffering from insanity are too much neglected, he says, in the intervals between attacks and when recovering from an attack of mania or some other form of intermittent insanity.

If patients in families predisposed to insanity were given the same careful attention and instruction they would receive if threatened with phthisis, they would benefit accordingly.

Of course one impediment in this course is the attitude of patients and their relations in giving as little prominence to symptoms of nervous derangement as they possibly can manage. Consequently an ailment rarely sees a patient until he has either had an attack of some form of insanity or at least has shown for some time decided eccentricity.

During an attack of melancholia, or of mania, we can only minister to the comfort of a patient and prevent him from injuring himself or others, but the management, during the time when he is slowly returning to his normal state, may determine the question of a second attack, or at least the length of time he will be free from one.

Sudden recovery from these disorders is the exception, and a very good means of determining their progress is by observing the character of sleep. Many cases will appear more rational during the day, but will continue to sleep no more soundly than before such seeming improvement began, and in such instances the improvement will show itself deceptive.

Among the symptoms of returning health are: "Improvement in sleep, general health, composure and interest, recognition of former delusions as such, mental improvement keeping pace with physical gain, return of menses, etc." To the mind of the author there is no surer sign though than "the cessation of decided fear of a return of the attack and of the patients' mortification at the supposed stigma which the attack has cast on them." The recurrence of symptoms of which the patient complained when sane, but which were lost during the attack of insanity, nervous headache, indigestion, back-

ache, etc., is another favorable sign. These symptoms usually recur in the inverse order to that observed previously. Backward steps —so great often as to stimulate relapse—may be expected, as an uninterrupted improvement is rather rare.

Patients and their friends frequently wish to stimulate the mind of a convalescent by light study, etc., but this is distinctly injurious in all cases where, as in mania, the mind has been in a state of unnatural excitement.

Piano playing and similar work requiring the minute attention for some time, is particularly to be avoided, even in cases of melancholia the effort to stimulate a patient's thoughts should not be continued when it becomes irksome to him. The necessity of absolute quiet and rest at the menstrual periods is mentioned because it is so often neglected.

In convalescence from acute mania, general paralysis of the insane, and from melancholia with any trace of suicidal tendency, the removal from the asylum should be postponed as long as possible, and change of any kind will prove ultimately injurious, though it often appears for a time to be causing marked benefit. The contrary course to this is beneficial in cases of melancholia which develop homesickness, and in cases of mild mania which find asylum life irksome and full of irritating restrictions.

The author goes further, and noting the general absence in this country of any convalescent homes for patients who have suffered from mental diseases, describes some steps which have been taken in Europe to meet this necessity. In France and Switzerland societies have been formed to furnish those discharged from insane asylums with money, tools, clothes, etc., and to supervise them to a certain extent in obtaining employment for them, and by investing any money they may save to as great advantage as possible.

In this issue is also a paper by Dr. Charles L. Dana on "The Localization of Sensations, etc."

IN THE PRACTITIONER

for December, the former editors Drs. T. Lander Brunton, Donald MacAlister and J. Mitchell Bruce announce their retirement in favor of Mr. Malcolm Morris.

Dr. Henry Ashby writes

"In the Ætiology of the So-Called Scurvy Rickets."

The author is unwilling to fully accept the current view that the anæmic condition seen in some cases of rickets is solely due to improper feeding, his own view being that in the cases which seem to be scurvy there is an increase of the anæmia which is always present in rickets. In the severe forms of several diseases, such as hereditary syphilis, a tendency to bleed from the mucous membranes, with very slight provocation is well recognized, and there seems to be no more excuse for the term "scurvy-syphilis" than "scurvy-rickets."

Criticizing the view often advanced that it is the absence of fresh vegetables, only, that leads to scurvy the fact is dwelt on that vegetables are absent from the diet of every child for the first year or two. Again, far from thinking that the children of poor parents escape this disease by picking miscellaneous scraps from the table, it seems more probable that those who live long enough to acquire this habit are hardy by nature, and that the weaker ones die of some disease of earlier manifestation. The weak children of wealthy parents, on the contrary avoid death for some time by reason of the great care they receive.

In the cases seen by the author he could always get a history of aggravated dyspepsia and its sequels. No case had up to the time of the onset of the disease been exclusively breast fed, and several had received food which would class with the antiscorbutics.

With the exception of breast milk the continued exclusive use of any food proves injurious and this is especially so if the supply of digestible fat is scanty. Milk, cream, whey, fresh beef juice, orange juice and cod-liver oil give the best results. Perhaps of even greater importance than a well selected dietary is plenty of sunlight and of fresh air.

Dr. James B. Ball has an article on

Chronic Lacunar Tonsillitis,

And recommends the use of a small hook-bladed knife to unite contiguous follicles and thereby encourage them to eject their contents.

The follicles are frequently found partially bridged by the swollen tissue, and the secretion confined in them by this. If a small knife, with a blunt pointed, hook-shaped blade, be inserted in one of these crypts, a slight motion will slip the tip into any communicating follicle and a slight pull will divide the intervening tissue. Several of these should be opened in this way, and to prevent rapid healing the writer then paints a solution of ninety grains each of iodine and iodide of potassium in an ounce of water over the surface.

If the tonsils are large enough and project enough they may be excised, but they are rarely of the proper shape.

Emptying the crypts and applying caustic without incision does not prove so satisfactory as this method.

Dr. Robert Turner gives some

Practical Points in Treatment of Venereal Diseases.

Cases of gonorrhœa seen early are given one-grain pills of aloin to cause purgation and lessen the likelihood of chordee and synovitis.

The abortive action of strong solutions of nitrate of silver is not acknowledged, and the writer uses instead one grain of morphine in an ounce of dilute nitrate of mercury ointment, applying the same three times daily to the anterior urethra by a match-stick wound with a small piece of absorbent cotton.

For epididymitis the application of leeches is followed by the free use of belladonna ointment and seems to give satisfaction.

Many of the cases seen were sailors and some of these had syphilis complicated with malaria. In such cases arsenic was preferable to quinine.

Men who had been to the African coast frequently presented phagedænic ulcers of the glans. These appeared early, were not syphilitic, healed promptly when dusted with zinc oxide and calomel, but they showed very plainly a phagadænic tendency and always left some deformity.

Dr. F. Ortan has a paper on

"Indigestion,"

using the case of a patient of his as the basis of his article.

This patient had become impressed with the idea that he had dyspepsia, and had by brooding over his condition and by the continual use of medicines lost in weight and spirits. The author recommended a free mixed diet of food chosen at will, and had the pleasure of seeing his patient resume his former healthy appearance. This sort of advice the writer thinks would cure most such cases and he goes to the extent of declaring that there is no such disease. He qualifies his statement, however, by saying that the various symptoms usually recognized as belonging to indigestion are those of a purely neurotic condition, and should be treated without consideration of the stomach.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

The Etiology of Pain in the Back.

Dr. S. Erben says (*Wiener med. Presse*): Pain in the back may be due to many different conditions. Other symptoms are to be sought. The eruption of herpes zoster, spondylitis, pyrexia (suggestive of infectious diseases or visceral inflammation). Examination of the abdominal and thoracic organs is necessary to detect a beginning pneumonia, pleuritis, pneumothorax, or tuberculosis. Interscapular pain, with dysphagia, might indicate mediastinal tumor, such as esophageal cancer, or an aneurism. Affections of the stomach, bowels, liver, and spleen, give pain usually confined to that part of the back between the fifth and ninth dorsal vertebræ. Constipation often causes dorso-intercostal neuralgia, gastric catarrh, ulcer, cancer, or atony, may cause severe dorsal pain. The genito-urinary tracts, especially in women, very often produce back ache. General conditions, such as anemia, chlorosis, spinal diseases, especially meningitis, of the dura mater, or the pia and tabes dorsalis, hysteria, and traumatism are also to be considered. All these being excluded, neuralgia or rheumatism is the sole condition.

An Epidemic of Vulvitis Occasioned by a Thermometer.

MM. Weill and Bergeon, of Lyons, have observed, in a hospital ward under their care, an epidemic of vulvitis occuring among young girls. There was nothing to explain its origin, for it was scattered irregularly among occupants of various beds. The mode of its origin was, however, rendered clear by a fresh outbreak following the admission of a typhoid fever patient. The contagion was spread by means of a thermometer which the nurse was in the habit of introducing into the anus of patients. The temperature was taken before and after each bath,—*i. e.*, sixteen times,—and therefore the gonococcus was deposited sixteen times and became a powerful contaminating agent. The thermometer was simply plunged in water carbolized 25 to 1000. The reporters caused the instrument to be cleansed in a 33-per-cent. solution of hydrochloric acid and the epidemic was promptly arrested. Three months later there was a recurrence, as a new nurse began to take temperatures and again employed the old 25 to 1000 carbolized solution. Contamination was conveyed by the part of the thermometer in contact with the vulva. Inflammation of the anus was in no instance caused.—*La Medecine Moderne.*

NEUROLOGY.

Criminal Anthropology.

In a recent essay on this subject Professor Lombroso, of Turin, describes what he terms the "criminal type." The features characteristic of this type are found in the faces of most regicides and assassins of presidents, notably Fieschi, Guiteau and Nobiling. To this type belong also the promoters and leaders of reigns of terrors, such as Carrier, Jourdan and Marat. Among noted anarchists he describes the bomb thrower, Ravachol. Lombroso says: "What first forcibly impresses the beholder of Ravachol's face is its bestiality. Its asymmetry is strongly marked; the nose deviates greatly to the right, the ears are implanted on the head at different heights, and the lower jaw is heavy, square and prognathic." In speaking of Ravachol's history, he says: "The pupil of a primary school until the age of fifteen, Ravachol left it almost absolutely illiterate. Designed by his parents for a simply mechanical trade, he abandoned his apprenticeship, because unable or unwilling to acquire

even its rudiments. He became a hopeless idler, committed thefts and circulated counterfeit money. He disinterred a corpse and robbed it of its jewels. He murdered an old hermit of eighty-four years, in order to steal his money. At about the same time, he attempted to kill his mother for a fancied offense. It was established during Ravachol's trial that his grandfather, Koenigstein, and his great-grandfather both perished on the scaffold, convicted of murder and arson. —*Alienist and Neurologist.*

OBSTETRICS.

The Treatment of Threatened Abortion.

In cases of unavoidable abortion, Dr. C. Marocco, an instructor in gynecology in the medical department of the University of Rome, (*Semaine Medicale*), advises tamponning the vagina with gauze moistened with glycerine, and the internal administration of the following prescription:

Phenacetine	o	30
Morphin hydrochlorat	o	01
Sacchari	q. s.	

This is to be administered in wafers every hour until three doses have been taken. Under this treatment the abortion is terminated almost without pain and within a period not exceeding twenty-four hours.

SKIN DISEASES.

Losophan in Ringworm of the Head.

Professor Ohmann-Dumesnil (*Quarterly Atlas of Dermatology*), writes as follows regarding the treatment of ringworm of the head:—"The treatment of ringworm of the scalp is far from being an easy matter so far as procuring a successful result is concerned. It is absolutely necessary to prepare the affected locality for the purpose of applying the proper remedial agents in a thorough and adequate manner. The hair of the head should first be clipped short. This being done, a good and thorough shampoo with sapo viridis is to be ordered, so as to cleanse the scalp as thoroughly as possible and, at the same time, dissolve all superficial portions of the parasite which may be lurking about. The next thing to do is to apply a good antiseptic solution, and for this purpose a one to five hundred bichloride solution, or some similar preparation will prove adequate. This having been done, the next thing in order is to epilate. Whilst epilation should be thorough, the least that is to be done is to epilate a half inch of the apparently healthy scalp surrounding a diseased patch. This effectually isolates the healthy from the diseased parts and prevents a further extension of the process.

This having been properly done, an application is to be rubbed in, whose purpose it is to destroy the sores and permit of a growth of healthy hair. There are many remedies suggested, but among the best is Losophan, combined as follows:

Losophan	2 drams
Axungiæ	2 ounces

M.

This should be thoroughly rubbed into the patch twice daily and continued for quite some time. Its persistent application will be rewarded by a good result in a comparatively short space of time."

Warts.

Professor Kaposi, in multiple warts of the face, employs the following:

Sulphur	grs. xx
Glycerin	grs. l
Pure con. acetic acid	grs. x

Apply locally to each wart.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JANUARY 18, 1895, TO JANUARY 26, 1895.

Colonel Joseph R. Smith, Assistant Surgeon General, will be relieved from duty as Medical Director, Department of the East, to take effect about February 5, 1895, and will proceed to his home where he is authorized to await retirement.

Leave of absence for twenty-one days to take effect upon being relieved from duty at Fort Warren, Massachusetts, is grauted Captain Edward R. Morris, Assistant Surgeon.

First Lieutenant Ashton B. Heyl, Assistant Surgeon, is relieved from duty at Columbus Barracks, Ohio, and ordered to Fort Thomas, Kentucky, for duty.

Major John V. Lauderdale, Surgeon, will be relieved from duty in the Department of the East, to take effect upon the expiration of his present leave of absence, and will then report for duty at Fort Omaha, Nebraska.

Lieutenant Colonel Henry R. Tilton, Deputy Surgeon General, is relieved from duty at Fort Omaha, Nebraska, and will report in person to the Commanding General Department of Dakota for duty as Medical Director of that Department. Colonel Byrne on being thus relieved, will report to the Commanding General Department of the East for duty as Medical Director of that Department.

NEWS AND MISCELLANY.

The Society for the Relief of Widows and Orphans of Medical Men of New Jersey, was incorporated in 1882 and has continued to grow both in influence and membership.

Since its organization 241 physicians of the State have become members; of which number 32 have died, 28 been dropped for various reasons, leaving at the present time 191 active members.

The Permanent Fund amounts to $1338.42, and it is intended eventually to allow small annuities to widows and minor children in cases of need.

The amount already paid to the families of deceased members amounts to $2478.00.

The total cost of running the society during the past year was $19.67.

ORIGINAL ARTICLES.

IMPORTANCE OF SURGICAL TREATMENT IN CHRONIC PURULENT OTITIS MEDIA.

GILBERT E. SEAMAN, M.D., MILWAUKEE, WIS.

It is not to go into detail in regard to the surgical treatment of chronic purulent otitis media, but rather to urge the importance of recognizing the necessity of such treatment when it exists, and point out briefly the dangerous sequelæ which are sooner or later liable to arise, and when we take into consideration the comparative frequency of these sequelæ, the successful treatment of the condition becomes a matter of prime importance.

St. John Roosa[1] says: "The almost inevitable consequences of the suppuration of the middle ear are dangerous to life and health of patients, hence the importance of the subject and the interest which every physician should take in arresting the advance of the disease."

It is almost an every day occurrence for the aurist to come in contact with patients suffering from a chronic purulent discharge from the ear, which has continued months or years, who inform him that they have been told by physicians that they need no treatment further than the routine injection of antiseptic solutions, or the insufflation of some antiseptic powder; or, perhaps, they have been advised that they will "outgrow" the trouble. Such advice is, as a rule, misleading, inasmuch as it engenders a false feeling of security which should not exist where there is a persistent purulent discharge from the ear. These cases may be divided into two classes as regards effects of routine treatment: 1st. Those cases which respond readily. 2d. Those which respond indifferently or not at all. It is with this latter class that we are specially concerned.

In a majority of these cases a careful examination will reveal the fact that there exists more or less necrotic tissue, such as dead bone, granulations, etc., or polypi, exostoses, and other products of inflammation; and when the disease has involved the deeper structures there are accumulations of effete material, the result of long continued inflammation, which the ordinary measures will not reach, and our efforts will prove of no avail unless we provide for free drainage. We must recognize and carry out the fundamental principles of surgery here as elsewhere. In those cases of suppurative otitis lasting over several months, there is nearly always present a condition which calls for surgical interference, and such surgical interference should be unhesitatingly resorted to as the only rational method of treatment. Otologists have quite generally recognized these facts within recent

years, but if one can judge from the number of cases of persistent otitis media of years standing, still "making the rounds," it is reasonable to conclude that there is still too much timidity in this regard, especially on the part of the general practitioner.

These cases, with very few exceptions, may be permanently relieved by removing the offending necrotic elements, granulations, polypi or other products of the disease, and such other obstructions to free drainage as may exist. This can generally be accomplished through the external meatus, but occasionally it may be necessary to resect the parts posterior to the meatus or open up the mastoid cells, establishing drainage through the ear.

These proceedings are comparatively simple, and when done with proper precautions are reasonably free from danger. But the anatomical relations and structure of the parts must be borne in mind, as the walls of both the middle ear and mastoid cavities are naturally thin, and when weakened by disease one might, with the smallest amount of undue force, enter the lateral sinus, labyrinth or brain cavity. The hemorrhage as a rule is of little consequence. In operating on the middle ear there is some danger of wounding the facial nerve, as it passes through the Fallopian canal. I may state, in this connection, that I have recently seen a case of facial paralysis produced in this way, in the practice of Dr. Bach. It did not appear until twenty-four hours after the operation, but the doctor was of the opinion that it was due to irritation at the time of the operation and a consequent congestion. The paralysis in this case responded readily to treatment by electricity, and was entirely gone in a few weeks. The results, however, are not always so favorable as this. Victor Horsley, Keen and others, state that the proximity of the nerve may be ascertained by the twitching of the facial muscles when an instrument comes in contact with its trunk. But I think the safer method is to locate the Fallopian canal and then control all hemorrhage so that it may be kept in view.

In cases of suppuration of the middle ear of long standing, the ossicles are frequently entirely destroyed, and after removal of remnants of the membrane, a thorough and careful use of the curette especially devised for this purpose, followed by appropriate after-treatment, is all that is necessary to affect a cure of the suppuration at least. The membrane should be thoroughly removed; not merely incised, but excised close to its attachment, especially at the lower part, so as to prevent lodgment of accumulations behind the membrane, and thus obstruct drainage.

Excision of ossicles. When there is only partial caries and ankylosis of ossicles it may be necessary to excise them. I will not go into detail in regard to this operation, but suffice it to say that it is by no means an easy matter. General anesthesia is not always necessary and many operators use a strong solution of cocaine instead, with success. The published reports of excision of the ossicles are decidedly favorable and where other methods are insufficient, it offers very encouraging hope. In regard to results, Burnett[7] formulates the following conclusions:

1. "This operation has not failed to stop suppuration in all cases of purulent otitis media in which the author has applied it.

2. "In 'attic' cases with normal atrium, the sole perforation being in the membrana flaccida, this operation is the only means of cure.

3. "By this operation, in cases in which the sole perforation is in the membrana tensa and is comparatively small, and while the purulency is limited to the anterior part of the drum cavity, the suppuration is checked before it reaches the drum cavity and mastoid disease, sinus thrombosis, and cerebral abscess are prevented.

4. "If any hearing exists before the operation it invariably improves after the operation.

5. "Vertigo, headache, tinnitus, and the ordinary attacks of acute inflammation, so common in chronic otorrhœa are entirely removed by the excision of the necrotic remnants of the membrana, malleus and incus."

Milligan[8] lately reported fifteen cases operated, with eleven cures; two improved and two still under treatment. Of the thirteen cases discharged, hearing was improved in eight, same in three, and worse in two. Milligan concludes that

in suppurative otitis with perforation of the membrane and caries of ossicles, local treatment has failed. That by excision of the ossicles all the symptoms are usually benefited and rarely made worse.

In the discussion of the paper the general opinion seemed to be in line with the ideas expressed by Milligan.

Many other operators, both here and abroad, report cases with a percentage of cures of the suppuration ranging from 75 to 85 per cent., with marked relief of the other symptoms and a decided increase in the power of hearing as a rule.

Before taking up the consideration of sequelæ, I might mention briefly the operation for the relief of this condition first suggested by Stacke,[4] of Erfurt, in 1890. He claims that the operation is particularly indicated where there is disease of the attic, and that, as a rule, the temporal antrum is involved in these cases.

Stacke makes an incision down to the bone, following the insertion of the auricle, excises the posterior wall of the meatus and clinches through the mastoid until the antrum is reached. He then removes the remains of the ossicles, membrane, whatever *débris* there may be present, making the attic and lower part of tympanum to form one cavity, and securing a free opening between the meatus and antrum, which is covered by a flap of skin and periosteum from the meatus. This is a difficult and formidable operation—practically a mastoid operation—and it does not seem to be justifiable or necessary in uncomplicated cases. The statistics of the operation as regards cure of suppuration and increase of hearing, certainly do not bear out the claims made for it

Sequelæ.—Among the most common consequences of middle ear disease are accumulations of masses of *débris* consisting of degenerated epithelium, fatty matter, etc., the so-called *cholesteatoma*, or pearly tumor. Virchow[5] says that nearly one-third of all fatal cases are due to these accumulations. On examination of an ear containing cholesteatoma, a yellow, hard mass will be seen, probably quite filling the middle ear, the odor is very offensive and the ear exceedingly painful. These masses can generally be softened up and removed by syringing, if they are situated where they can be reached by such measures. But if located deep in the middle ear, or impacted in the mastoid cells it is, of course, necessary to resort to surgical interference, either the use of the curette or opening of the mastoid. Cholesteatoma are very liable to recur.

Exostoses, excepting congenital, are with few exceptions due to middle ear suppuration. They can generally be removed with the curette, but occasionally are dense and require the use of the chisel, or the dental engine and burr, as first suggested by Mathewson.

Mastoid disease, periostitis and caries with pus formation more frequently results from purulent otitis media than from any other cause. In a summary of fifty-nine cases reported by Roosa,[6] twenty-five were due to this trouble. The statistics of various authors I have at hand, place the proportion of mastoid cases due to ear disease at from one-third to one-half, and when we take into consideration the close relationship of the middle ear and mastoid, it is easy to understand how extension of inflammation from one to the other takes place.

It is not always an easy matter to differentiate between periostitis and caries of the mastoid, as frequently the symptoms are very similar. Frequently however, in suppuration of mastoid, the ordinary symptoms of periostitis-redness, swelling, etc., are absent, and excessive pain in the ear, with perhaps a decrease in the discharge, and rise of temperature are the only indications. Where these symptoms exist, no time should be lost in applying surgical treatment.

Necrosis of temporal bone, more or less extensive, not infrequently occurs as a consequence of this disease, and there are a number of cases on record where nearly all of the bony structures of the internal ear have become carious and been extracted as sequestra during the life of the patients. This is one of the most fatal complications and the symptoms vary widely, according to the parts involved. The canal in which runs the facial nerve may be included in the necrosis, or there may be engorgement of the nerve during the acute exacerbation and facial paralysis complicate the condition. The prognosis of the paralysis, however, is generally good. The treatment in addition to the application of general principles must necessarily be largely expectant, removing the sequestrum when it is possible.

Meningitis is a comparatively frequent and very fatal complication, especially in young children. It is, as a rule, secondary to other complications, such as cerebral and mastoid abscess, etc. Meningitis may be produced by entrance of morbid material into the circulation or by extension of inflammation from the bone to the dura and meninges. The symptoms do not differ materially from those of meningitis due to other causes. It seems to be the general opinion that surgical treatment is of little use in these cases. Pitt, quoted by Burnett,[7] says a fatal termination will be more frequently prevented "when it is recognized that it is desirable to operate sooner than we have hitherto done in those cases of ear disease in which there are severe local symptoms."

Cerebral abscess, extradural, subdural, and abscess of brain substance proper, more frequently result from middle-ear suppuration than from any other cause. According to good authority fifty per cent. of all cases arise in this way. It is not necessaay for caries of bone to exist in order that abscess may be developed. The purulency may involve the internal ear and, by extension along the membranes, cause a septic inflammation and result in the formation of abscess. The symptoms of abscess generally follow cessation of the discharge, and are severe headache, either general or local, due to pressure, slowness of pulse and respiration, vomiting, sluggishness of the mental faculties and other symptoms according to the location of the abscess. There is generally a rise of temperature, but if the abscess be extradural or subdural, it is frequently normal or subnormal. As the greater number of abscesses from ear disease are situated in the tempero-sphenoidal lobe, symptoms of pressure in this region, such as motor aphasia and paralysis of the face and extremities, will frequently appear. Owing largely to recent advances in the matter of cerebral localization, the indications for surgical interference are now clearer and while the results are not all that could be desired, they are very encouraging.

Thrombosis of the lateral sinus and phlebitis are occasionally met with and often give rise by metastasis to septic pleurisy or abscess of the lung. The symptoms of thrombosis are rigor, pyrexia, tenderness behind the mastoid, pain in the occiput and neck, and if the clot has extended along the jugular vein there will probably be tendernsss and inflammatory thickening in the region of the vein and carotid artery. The discharge from the ear will have ceased in the majority of cases. This condition was formerly considered to be an extremely fatal complication. But within the past few years it has been more frequently recognized as it occurred, and the results of ligating the internal jugular, as first suggested by Zanfel, in 1889, have been satisfactory. The best statistics I have been able to find are those of Lane.[8] He lays open the sinus, ligates the jugular below any thrombus encountered, and irrigates the septic surfaces. Lane[8] reports ten cases with nine recoveries. In a series of thirty-two cases gathered from various sources by Keen,[9] nineteen recovered and thirteen died after this operation. And Dr. Macewan in his recent textbook, mentions twenty cases operated, with sixteen recoveries. Thus it will be seen that the results of operation in this condition are decidedly favorable.

Malignant sarcoma, carcinoma and tuberculosis are said to be among the rarer complications of purulent otitis media.

I present this paper with the hope that it will serve to impress more firmly the necessity for surgical procedure in chronic suppuration of the middle ear. In regard to temporizing with this condition Keen has to say: "A case may go on for fifteen or twenty years, but the day of reckoning may at last come. and when it does come, it comes like a whirlwind."

INTESTINAL OBSTRUCTION; DOUBLE HAIR LIP; GASTROSTOMY TUBE; HEPATIC ABSCESS.*

ROSWELL PARK, A.M., M.D., BUFFALO.

Friday night after dinner, a man aged forty-eight, was seized with severe, rather indefinite, abdominal pains which suggested appendix inflammation. Once or twice before he had similar attacks but not quite so severe. He had to go to bed on account of the pains. An injection was given, as there had been no action of the bowels, anodynes also, and the man grew no worse till Monday afternoon, when he had fæcal vomiting, and the same night he vomited half an ordinary chamberful of fæcal matter. Tuesday morning I saw him with the medical attendants. At that time he had not vomited since the night previous, his pulse was good and full. There was much rumbling and peristaltic action of the bowel as the result of large injections, but the bowels had not moved. I suggested a more powerful enema of a saturated solution of magnesium sulphate, and at the same time advised that if there was any return of the fæcal vomiting the patient should be brought to the hospital and operated on at once. At six o'clock that night I operated, making the opening in the middle line. While exploring the intestine, running my finger along its coils, all of a sudden something gave way before my finger on the right side of the abdomen and there was a gush of exceedingly foul pus. This ran everywhere and some of it must have escaped into the abdominal cavity. I had not expected pus, yet I had proceeded with the greatest caution, using barely enough force to rupture the most delicate peritoneal adhesion. The intestine was at once removed, coil by coil, until the patient was nearly eviscerated. Finally I found a place where there had been a nest of adhesions shutting off a cavity between several loops of bowel, and in this pocket foul-smelling pus had collected. After disinfecting this with a hydrogen peroxide solution, I came upon two loops of bowel, one above the other, and both behind the abscess. These had been doubled up so that nothing could pass through them. Without much difficulty, I separated the adhesions which bound the intestinal kinks, once more disinfected the whole abdominal cavity, washed it out thoroughly with hot water and put in a drainage-tube. I put back the bowels and closed the external incision down to the tube. This morning the man's pulse is good, his temperature is 102° F., his general condition is as favorable as I could expect. The chances are naturally against recovery, yet I have some hope the man will get well.

Of the causes of intestinal obstruction, intussusception and volvulus are the most common; adhesions either freshly formed or old peritoneal bands not uncommonly obstruct the intestine but this case is a rare one. I presume this trouble began with some mechanical obstruction, then there was a little damage to the peritoneal coat, just enough to cause some exudation. But exudate causes adhesions and adhesions more obstruction to the bowel, and more exudate, so that the sequence runs in a vicious circle. The exudate undoubtedly became infected with the colon bacillus.

The case is highly interesting pathologically, rare clinically, and demanding relief surgically.

DOUBLE HARE LIP

This is a little boy who, they say is five days old. It would be insufficient to diagnose his case as a hare-lip. You will note that there is a complete fissure of the lip, projecting into the maxillary bones. The lip is represented in the middle by what the Germans call a *philtrum*, which projects like the snout of some animal. It is not merely a loose tag of soft tissue which can be readily approximated to the lateral portions of the lip, but it is connected to cartilage with centers of ossification. In order to get it back in line with the rest of the lip, I shall remove a

*A clinical lecture at the Buffalo General Hospital.

V-shaped piece of cartilage. My opinion is that, on account of the shock, which is always relatively greater in infants than in adults, it will be better to finish the restoration of the lip at a second sitting. At that time, the margins of the double cleft in the lip will be freshened and the parts united by the aid of a hare-lip pin.

This condition is not a perversion of growth along unnatural lines, but is the persistence of a tripartite arrangement which is normal in early foetal life and which usually coalesces later.

GASTROSTOMY TUBE.

This patient is a girl upon when I performed gastrostomy some weeks ago, on account of occlusion of the pharynx from congenital syphilis. At the time, the operation was necessary to keep the girl from starving. Of late, however, the relief of the pharynx from irritation and the action of drugs have cleared up the granulations in the throat so that she has taken food through the œsophagus and the fistula has closed. It is not at all certain that she will long be able to nourish herself by the natural passage as it is even now difficult for her to do so and, we have had a tube constructed to facilitate feeding through the fistula. The canula is a silver tube with a shield which can be set at any point by a screw. A rubber tube with attached funnel can be slipped over the metal tube, and the nourishment can then be poured in. It is easy to reopen the fistula and you can see that the stomach contents appear at once in the opening.

HEPATIC ABSCESS.

Some time ago you saw a case of abscess of the liver, which was opened and drained. The man was sent to his home in Pennsylvania with a drainage tube in place. The opening, however, does not now permit as free drainage as is necessary and I purpose enlarging it to day. There have probably been formed wide adhesions between the surface of the liver and abdominal wall, so that there is now little danger of opening into the abdominal cavity. It will probably be necessary to resect one or two ribs to follow the sinus to the bottom, and this can be done with cutting forceps. When I was a medical student, resection of a rib was a very unusual, even serious operation; it is now considered a simple procedure. There is no trouble to be feared providing you have control of your instruments and can maintain asepsis. Ordinarily it is necessary to keep out of the pleural and the peritoneal cavities by following the bone closely. The periosteum is intimately connected with the serous membranes, and both together should be stripped from the rib by an instrument having the proper curve to prevent it slipping through the soft parts. It is simply a question of dexterity to keep such an instrument always in contact with the bone. The other bug bear of rib resection was the intercostal artery, which runs in a grove in the under and inner aspect of the rib. But with aseptic methods, an artery running in a bony channel affords as much security as one could ask for. It is not necessary to ligate such a vessel, for one can easily plug the bony channel, or, in the case of a rib, all that is necessary is to crush the bone with strong-beaked forceps.

Typhoid Fever.

In the management of typhoid fever, Dr. Adolph Kœnig, of Pittsburg, Pa., has used with satisfaction, the following:

Guaiacol	} fl 3 ij.
Glycerini .....āā	
Alcoholis	fl 3 iv.

M. Sig.—Five drops in whiskey and water every two two hours.

—*Food.*

Treatment of Delirium Treamens.

In the *New York Med. Jour.* Bellamy concludes an article as follows:

1. Delirium was controlled with greater rapidity and safety by trional than by other hypnotics.

In the majority of cases a marked stimulant effect was observed, possibly on account of the methylic and ethylic elements which enter into the composition of the drug.

3. On account of the low temperature noted in all cases, trional must posess antipyretic properties, thereby simulating its allies of the phenol group.

4. It was always well borne by the stomach, and in one case was rapidly absorbed when administered per rectum.

5. No unpleasant after-effects were observed, and in all cases recovery was speedy, with the exception of two.

LEAD POISONING.*

PROFESSOR WANNEBROUCQ, LILLE, FRANCE.

Lead poisoning may take place under the various conditions, but it is most frequently of professional origin, at least in our portion of the country. Here, as you know, our white lead is prepared according to the Dutch method, and during the various processes of its manufacture much dust is produced which contains a great deal of the carbonate of this metal, and which, in the majority of cases, is the cause of the poisoning Absorption may take place in various ways, but more particularly by the digestive and respiratory tracts. Lead, when introduced into the system, acts especially upon the nervous system in its central as well as peripheric portions; but at the necropsies it is also found in other portions of the body and especially in the liver, the spleen and kidneys. It also has an action upon the blood by decreasing the number of red blood corpuscles even to one half, increasing those that remain in size and impoverishing the coloring matter.

Lead poisoning is observed, clinically, as various symptom complexes either isolated or associated, among which is most frequent that which, according to my ideas, is termed lead colic. This latter form is presented by two patients now under treatment in the hospital.

The first is that of a young man of twenty-nine years and a half, who is dirty, careless of his person, regardless of the least hygienic measures, addicted to alcohol and therefore particularly susceptible to the deleterious action of the metal. Scarcely fifteen days after his entering the workshop he experienced the first symptoms: lack of appetite, disgust of food, nausea, vomiting, constipation and general weakness, but it was only later when he noticed sharp pains in his abdomen that he decided to enter the hospital.

At the examination we found him pale, anemic, with a subicteric tinge of his conjunctivæ and skin. This peculiar color, which is especially noticed in lead poisoning, is not due to the coloring matter of the bile, bilirubine, for an analysis of the urine will not yield the characteristic reaction, but, on the contrary, it is the product of the destruction of the red blood corpuscles and the impregnation of the tissues by the hemoglobine and methemoglobine. His pulse is small and slow; if one take a sphygmographic tracing, one will remark that the ascending line is short and but little accentuated while the descending one is long and almost horizontal. His breath is foul, an other characteristic sign of this disease, due not only to a lack of proper care of teeth but also to exhalations of sulphuretted hydrogen from long retention of the feces in the intestines.

For several days he has suffered from violent abdominal pains, an actual colic, as he says. He has no appetite and vomits frequently. The vomited matter which is quite abundant, is composed of bile mixed with mucus. For the last eight days he has had no passage of the bowels and the different purgatives which he has taken while at the hospital, have been without effect. He has no fever; on the contrary, his temperature is slightly below normal.

These symptoms have directed us into the right path for a proper diagnosis, but if we continue our examination we shall find from the blue line along his gums and the nature of the pains, the characteristic signs of his disease. His teeth are covered with a thick coating of tartar and in this tartar near the gum we notice a small and blackish line, almost on the gums, and at the roots of the teeth. To be precise this line is not exactly black as it is but a slight and recent deposit of tartar, so that, seen by refraction, it has rather a violet color than a very pronounced dark. This line is not only situated upon the teeth but also upon the margin of the gum itself.[1] Some writers have asserted that it was due to small and capillary emboli in the vascular loops of the edge of the gum, but I rather think that this theory is not tenable and that it is simply dependent upon the introduc-

*A clinical lecture delivered at the Hospital Saint-Sauveur, Lille, France. Translated from Le Nord Medical, December 15, 1894, by F. H. Pritchard, M.D.

tion of minute particles of lead into the tartar and the gum which is transformed into the black sulphate of lead by the action of the sulphohydrate of ammonia, which is formed in the mouth. This sulphate penetrates, little by little, into the mucous membrane and becomes fixed as a sort of tatooing, aided by the mechanical action of the lips upon the roots of the teeth. We have a support to this theory in the second patient, for if one lift his upper lip you will notice a sort of tatooed line on the mucous membrane of his lip which corresponds to the portion which lies against the roots of his upper teeth. Whatever be the proper explanation of this characteristic, the line is present in our first patient, and forms a sign of great value in diagnosing lead poisoning.

We find a second in the analysis of his pretended colics of which he complains. You will observe that these pains are not situated in the abdominal region in all its extent, but that in this patient they are limited to the region of the two recti. If one press upon them at any point, the patient will complain of violent pain, yet in the immediate vicinity of these muscles nothing of the kind is noticed. One may press the abdomen inwards in any other region without giving rise to the slightest pain; on the contrary, we may raise a fold of skin and pinch it and no painful reaction follows. Therefore, the subjacent portion of the abdominal wall is the seat of the pain and not the intestine, for, at the sides we may press upon them with considerable force without pain. The pain is, indeed, in the muscle itself, of which we have a striking demonstration. If one press firmly upon the upper insertions of these muscles, on the costo-xiphoid ligament at the anterior portion of the fifth, sixth and seventh costal cartilages we will produce pain; the same reaction will follow pressure upon their pubic attachments and here posterior to them we find only the bladder. Let us proceed still farther, for the patient is not very fleshy and the experiment is easily carried out. If we pinch between the thumb and index finger the lower insertion of the rectus taking care not to depress the abdominal wall we notice that pain is provoked. Hence, this patient does not suffer from colic as he says, but from a myalgia of the recti. But this muscular pain is not always limited to these muscles for it may affect the obliqui as well as the transeversis, while those of the posterior portion of the wall are rarely involved. Occasionally it has been observed to extend to the chest muscles, but the muscles chiefly affected are those of the abdomen and secondly, the adductors of the thigh. Our patient has no disturbance of the urinary passages. He has no albumen in his urine, but the quantity of urea is considerably reduced in proportion.

Treatment should be first and foremost directed towards relief of the pain. This result is generally obtained by applying a narrow mustard plaster along the affected muscles when there is no cutaneous hyperesthesia. These sinapisms should not be left on long enough to produce either blisters or eschars. In case of cutaneous hyperesthesia we prefer local applications of tincture of iodine. Under the influence of this treatment the muscular pain rapidly disappears, and with it the vomiting; the abdomen which has been tense and hard becomes soft and normally distended, and if not too large a mass has formed in the rectal pouch the patient has a passage of the bowels, for the pain, the principal cause of the constipation, has vanished. If evacuation of the bowels does not follow I usually give a purgative. Our patient has been cured in a few days; the pain disappeared, the vomiting and constipation ceased and the processes of nutrition resumed their normal functions.

But I have said nothing with regard to treatment of the primary cause, and one must attempt to cause elimination of the lead accumulated in the tissues. The metal in the skin may be removed by two or three sulphur baths, followed the next morning by one of soap and water. That in the intestines may be precipitated by the use of sulphurous mineral waters. As to that which has been stored up in the different organs it is best removed by a progressive renovation of the histological elements and keeping the emunctories in working order, particuliarly the kidneys and liver. Here hygeine takes the place of remedies. The iodide of potash which is sometimes administered, would seem to me to have more a harmful than a beneficial influence, for on contact with lead it forms an insoluble sulphate.

Our second patient is also affected with lead poisoning. He is a young man,

twenty-nine years of age, who doubtless, after trying his hand at all the trades, has finally ended in a lead factory. He is an inveterate drinker, his breath is fetid, he has suffered from vomiting since his entrance into the hospital, complains of obstinate constipation for which several purgatives have been given in vain, he presents a pronounced blue line along the gums and suffers from pains not only in the recti muscles, but also in the obliqui and transversi. On the same day that he entered he had no exaggerated cutaneous sensibility, but since then the dermalgia has appeared. This patient also exhibits some of the signs of hysteria, as abolition of the pharyngeal reflex, plaques of anesthesia, tremor, but no narrowing of the visual field nor hyperesthesia of the spine.

We treated his dermalgia by local applications of tincture of iodine; it yielded quite rapidly, but the myalgia was slower to disappear. We were obliged to employ here not only a mustard plaster, but also hypodermics of chloroform. This latter procedure, which we use with success in obstinate cases, consists in injecting into the region of the painful muscles two hypodermic syringefuls of a mixture of equal parts of chloroform and oil of vaseline. Thanks to this measure the pains ceased and with them the obstinate constipation and the vomiting.

These various measures are not the only ones, for others have been praised. Briquet treated lead colic by faradization of the affected muscles. This is, however, too painful, for one must have a care to faradize the skin only and not the muscles, which are apt to be thrown into painful contractions. Injections of morphine are also used, but they have the serious inconvenience of increasing the constipation; belladona, antipyrine in doses of two, three, four and even six grams, have been administered, but they have the inconvenience of not always being tolerated while they have produced gastralgia and gastritis. Professsor Combemale has tried olive oil in large doses of a glass a day, but I doubt if this remedy in such doses would be well borne by the greater number of lead patients, who are so prone not to bear even the mildest beverages. We therefore hold to the tincture of iodine for the dermalgia, to sinapisms for myalgia and sulphurous baths and drinking of sulphurous waters to eliminate the metal. These measures have rarely failed us in the hundreds of lead patients whom we have treated in this manner.

Diabetes Mellitus.

Solis Cohen uses codein in certain cases of this disease in gra. ually increasing doses up to 12 grains or more daily:

Codein phosphate	gr ii
Alcohol	ʒiv
Dilute phosphoric acid	ʒii
Glycerin	ʒvi
Solution of hydrogen dioxide (10 volume) to make	ʒiii

Dose: two teaspoonfuls in 3 ounces of water.

—*College and Clinical Record.*

The Blessedness of Beards.

It is to be feared that too many men deprive themselves of what Shakespeare calls, "Valour's Excrement," without counting the possible cost. Whether the beard be an ornament to the masculine countenance we must leave the ladies to decide. It certainly has its uses in hiding a weak chin, and in some cases it seems to be cultivated as a vicarious compensation for a hairless scalp. It is not, however, in its cosmetic so much as in its hygienic aspects, that the blessedness of the beard—in which term we include the whole of the harvest usually claimed by the razor—is most apparent. That it is a safeguard to the throat is gen erally admitted, and writers of authority have insisted on its value as a protection against toothache and facial neuralgia. This is a goodly sum of advantages to the credit of the beard. Dr. Chabbert, of Toulouse, has, however, yet more to say in its favor. According to this practitioner, the beard seems to be a very efficient defense against that form of facial paralysis, which is caused by cold. This affection is far more common in women than in men, though the latter are, of course, more exposed to the cause that produces it. Professor Andri, of Toulouse, has seen several cases of this affection in women, but not one in man—he has heard of one, indeed, which would appear to be an excellent example of the exception which proves the rule, for the patient was a "lyric artist" with the faccia di musico, so distasteful to Lord Byron. Professor Pitres, of Bordeaux, has seen twelve cases in women and only two in men.—*British Medical Journal.*

COMMUNICATIONS.

RHACHITIC DEFORMITIES—ETIOLOGY, CLINICAL HISTORY, AND LESIONS.*

A. JACOBI, M.D., NEW YORK.

Our subject is the etiology and the lesions of rhachitic deformities. By way of introduction I would say that rhachitic deformities are something new in our country. You have seen so many of them that undoubtedly the younger men here do not remember the time when there were no rhachitic deformities amongst us. Thirty years ago there was no rhachitis, except very rarely a stray mild case. At that time, when I spoke of rhachitis and endeavored to demonstrate a case in my clinic, I had to hunt considerably for material to illustrate this condition. When, twenty-two years ago, I wrote a paper on the first cases of craniotabes I had seen in New York, it was, with the exception of one, by Parry, of Philadelphia, the first paper on this subject ever written in our country. The subject of rhachitis, therefore, is a comparatively novel one. Since that time immigration has been going on, and the poverty-strciken people from the slums of Europe have been accumulating here. As with the greater facilities for transportation science has been equalized all over the globe, so poverty, bad air, and want of every description have equally spread constitutional diseases here. Since then we have seen much rhachitis here. Thus it is that the treatment of rhachitis in the future, although it will always remain medical, will also be a social question.

The principal causes of rhachitic deformity are numerous—the rapid growth, the thick epiphyses, the soft diaphyses, the condition of the ossification cartilage, the traction of the muscles, the debility of the muscles, and the pressure of the atmosphere. The locality where the deformities are found depends largely upon the intensity of growth. Growth is most intense in the young child: (1) In the cranium; (2) in the chest; and lastly only in the extremities. I recapitulate only what you all know when I speak of the rhachitic head, with the thin skin, the dilated veins, and the open sutures and fontanelles for two, three, four, or even nine years, as I have seen it. The edges of the sutures are irregular. Such a head is usually large—actually larger than the normal head—relatively it is very much larger when compared with the frequently small body. It is so large that it resembles sometimes the hydrocephalic head. Indeed, some of these heads are to a certain degree hydrocephalic; some are entirely so. Most of them are brachycephalic, quadrangular, with depression on top. In a peculiar class of cases, first studied by Virchow, that of the cretins and semi-cretins, rhachitis is combined with a premature ossification of the occipito-sphenoid synchondrosis. In this condition the base of the skull is shortened. At the same time there is a deep grooving of the root of the nose, the eyes are widely separated from each other, there is shortening of the vomer, and the flat palate, so characteristic for cretinoid conditions. Not infrequently the occiput is slightly flattened, and the oblique diameters are sometimes not equal, so that one side may appear to be entirely flattened. This is particularly the case when we deal with rickety softening of the cranial bones —craniotabes. In such cases there is much perspiration, with loss of hair on the occiput; the veins are more dilated, the skin thinner and paler than in the average case. In these cases of craniotabes one side may be flattened and the other side bulging. The head may even appear to be triangular. Where one side bulges out, and one side is flattened from pressure, the forehead is very prominent, the frontal bone may have three to five times its normal thickness, because of an

*Read before the American Orthopedic Association, 1894.

immense amount of new periosteal soft growth between the periosteum and the bones, which produces a marked deformity of the forehead. This is not always a temporary affair. It is true that craniotabes may leave no trace if it gets well sufficiently soon; but when there is much deposit under the periosteum, it will sometimes remain. When calcification takes place very suddenly, then the thickening of the bone will remain unabsorbed for life. As a rule, however, most of such thickenings are absorbed.

The condition of the teeth is certainly one which should be considered in connection with rhachitic deformity. The teeth appear late or irregularly; when early, the intervals between the first crop and the second, or between the second and third are very long, sometimes six, eight, or ten months. The teeth are frequently discolored, and they decay very easily. Sometimes, however, we find in the second crop that the teeth are very hard and very yellow. Not infrequently we see "Hutchinson teeth" in rhachitic children. This is one of the reasons why Parrot got the idea of explaining every case of rhachitis as the result of syphilis. The lower jaws are short, narrow and very low; the angles very sharp and prominent. The aveolar processes turn inward. Thus the teeth of the upper jaw do not cover those of the lower jaw. The chin in some cases is very low. From the foregoing remarks it will be seen that well-marked rhachitic heads present a very peculiar appearance.

The trunk in rhachitic persons is very short. The clavicle shows much periosteal thickening; it is very frequently bent forward by the pulling of the muscles, and there is not infrequently an infraction between the middle and anterior thirds.

The chest is the seat of a great deal of deformity. It is frequently triangular, sometimes quadrangular; the dorsum is flat and the scapula clings to the body. The ribs, being soft, form a groove in which the arms are frequently buried. There is a predominance anteriorly. On account of the atmospheric pressure laterally above the diaphragm, there is a horizontal groove, called "Harrison's groove." As there is compression above the diaphragm the lower ribs stand outward. As the chest is compressed laterally the sternum is made to protrude, particularly about the third and fourth ribs, and the antero-posterior diameter lengthened. The ribs are prominent at the ossification points. On the cartilages there are frequently nodulations; a complete rosary may be developed quite early. I have seen it at the age of two months, and a case has been published in which there was a complete rosary in a baby of only three weeks. In these extreme cases, the sternum is flat, and the manubrium stands out. Frequently it is pressed down above so as to stand out at an angle at its lower end. The lower end of the sternum may be retracted while the ensiform process protrudes.

Kyphosis is very frequently seen in these cases. It is often but an exaggeration of the normal curvature. Scoliosis has mostly its convexity to the right with compensation above and below. The spinous processes are very frequently directed to the concavity. The intercostal spaces are very narrow on the left side, because there is less curvature of the ribs, and the ribs are bent out.

In the grown-up woman the antero-posterior diameter of the pelvis is shortened. This is not seen to the same extent in the babe. In the normal baby the pelvis is small and the sacrum very steep, not concave as in the adult. Therefore, when compression has taken place because of softening, it is still smaller, so that it is often quite difficult to examine the pelvis satisfactorily; the sacrum may be so changed as to give rise to a convexity inward and contraction of the two sides. This narrowing may be due to the mere fact that the softened bones are compressed on the pillow, or by the arms of the nurse, a pressure which is slight, it is true, but quite sufficient. In very mild cases the symphysis is changed but little. In a number of instances, however, it will be found to be bent forward, and thus in very early rhachitis the rhachitic pelvis may be very similar to the pelvis deformed by osteomalacia. This is contrary to the usual description in the books of obstetrics.

The extremities suffer in different ways in all their parts, the epiphyses and diaphyses, the periosteum, and the epiphyseal cartilages. The epiphysis is frequently thick and painful, particularly on the forearm and tibia. A number of cases of so-called "growing pains" are simply in-

stances of rhachitic epiphysitis. Sometimes the thickening is very considerable; in most cases it is uniform, but in some it is more developed laterally. This is particularly the case on the upper part of the thigh. The diaphysis is usually bent. Semi-fractures take place on the arm, clavicle and legs, from a very trifling application of force. The periosteum, however, being soft, always acts as a shield to the inflamed bone when exposed to the danger of fracturing. In all those cases in which there is much curvature, particularly in the lower extremity, the concavity is inward, and on the forearm and thighs it is very often anteriorly. The difference in the direction of the curvatures depends on the influence of the muscular traction or of the weight of the body. In the very young the concavity of the lower extremity is inward, because of the effect of the flexor muscles. When the bones become, or remain, soft in those who attempt to walk, the weight of the body results in outward curvatures and torsions of many kinds.

The ligaments are very flabby, and give rise to the flat-foot in children that stand up and attempt walking. The periosteum suffers a great deal and in different ways. It is softened and exhibits a thick layer of rhachitic deposit. Calcification occurs in time, and then the diaphysis will be much thicker and harder than in normal conditions. The bones of rhachitical patients, when recovered, are solid and able to stand a great deal of hardship in later life.

In the rhachitical periosteum there may be hemorrhages. Not infrequently in bad cases of rhachitis, and in those cases which in the course of general ill-nutrition develop purpura, there are hemorrhages under the periosteum in the lower and upper extremities. Such cases of decided rhachitis, and those which exhibit similar hemorrhages without being markedly rhachitic, have been thrown together under the heading of, in this country, "scurvy," and abroad, "acute rickets." In all of these cases the children are ill-fed; there is a great deal of pain in the lower extremities and feet, sometimes with and sometimes without periostitis. The hemorrhages will heal and leave a thickening in part of the cases. Hemorrhage of the gums is not a requisite for the diagnosis; it may be absent in those who have no teeth, or who have, and present even where there are no teeth.

Finally, deformities consisting of shortening of the whole limb are due to the early calcification of the epiphyseal cartilages, for it is on their physiological function that the length of the diaphysis depends. When calcification is complete the growth of the bone and that of the limb ceases.

I wish to remind you that rhachitis is a general constitutional disease. In it we have to deal not only with the bones, but with the general system, particularly with another part of the ~~locomotor system~~—the muscles. The muscles suffer just as well as the bones in rhachitis, and give rise to certain deformities. Both voluntary and involuntary muscles are affected. What has been called rhachitical pseudo-paralysis is not paralysis; it is simply a weakness of the muscles and nothing else. We should have been spared this new term. The muscles are simply poorly developed, and in consequence they are easily fatigued. The involuntary muscles suffer in the same way.

While the muscular tissue is poorly developed, fat is liable to be ample. Rhachitical children, unless emaciated by pulmonary or intestinal disease, are apt to be heavy and rotund, and their weight and appearance are often mistaken for healthy development. But they are flabby, anæmic, and not capable of resisting the attacks of ordinary disease like well children. They prove, moreover, that weight alone is not the measure for healthy and steady evolution.

The muscles in such subjects are flabby, and, consequently, the stomach is apt to be dilated, and the muscular layers of the intestines are apt to give way, thus giving rise to large, flabby abdomens filled with gas, on the surface of which are dilated veins.

The expansion of the intestines, owing to the weakness of the muscles, gives rise to constipation. This constipation is characteristic. Rhachitic children become constipated very early. It is sometimes the first symptom of rhachitis, and shows that the muscles participate in the process at a very early stage. It may begin at the second or third month of life in a child presenting evidences of fairly good nutrition; and it at once leads us to suspect rhachitis. Some deformity of the

abdomen may be due to the spleen, liver and kidneys. In consequence of "Harrison's groove" the liver and spleen are not infrequently displaced, and these organs for the same reason may appear larger than they really are. The kidneys may be found floating. Most of the cases of floating kidney occurring in children that I have met with were in rhachitic patients, showing "Harrison's groove" well developed. But there are cases in which the spleen and liver are actually enlarged from slow congestion and interstitial hyperplasia. They cause the same deformity that is occasionally seen in syphilitic subjects. This is another reason why Parrot came to the conclusion that every case of rhachitis must be syphilitic.

RHACHITIS.—ITS VARIOUS MANIFESTATIONS—DIAGNOSIS, DIFFERENTIAL DIAGNOSIS AND PROGNOSIS.*

BENJAMIN LEE, M.D., PHILADELPHIA.

The essence of rickets being the failure on the part of the system to assimilate the earthly salts, and especially the phosphate of lime, we should naturally look for its principal manifestations in those tissues of which lime and phosphorous, singly or in combination, form essential constituents, namely, the nervous and the osseous tissues. And the nervous tissue being more sensitive to irritation and more prone to rapid trophic changes than the osseous, it would not be unreasonable to expect that the results of such imperfect nutrition should first manifest themselves in the perturbation of functions peculiar to it, even though the organic processes of impairment might be going on simultaneously in both. For reasons which we do not understand, however, the nervous disturbances may sometimes be so slight as to elicit little attention, or, even if somewhat marked, may be entirely misinterpreted even in cases in which the degeneration of the osseous tissue becomes considerable. The comparative rarity of the affection in this country is apt to throw us off our guard, and many cases of this disease run their course under the name of gastro-enteritis, intestinal indigestion, intestinal catarrh, and so on, all of which conditions, indeed, may complicate the initial disease. In thus broadly characterizing the nature of this disorder, I do not forget the fact that it has been demonstrated that arterial enlargement or dilatation is a frequent, if not an invariable, accompaniment of the other changes; but it appears to me more philosophical to regard that as one of the morbid processes due to the vice of nutrition rather than as the cause of the alterations in the tissues referred to.

It is a well-established fact that children may be born rhachitic. In that case the symptoms of faulty nutrition of the nerve-centres may be present from birth. Otherwise they may develop at any time in the course of the first three years of life, but oftenest during the period of lactation. It is not uncommon for a rhachitic infant to appear vigorous and robust during the first two or three months of life, and even to take on an excessive amount of fat. It will usually, however, offer indications of indigestion, especially in the intestinal tract. This may be accompanied either by obstinate constipation or by diarrhœa; at first oftener by constipation. Frequent attacks of severe colic are not uncommon. The abdomen is tumid. Such infants are poor sleepers, having restless, disturbed nights. It goes without saying, that we should be more on the alert for early indications of this trouble in bottle-fed infants than in those at the breast. This condition may continue for from one to three or four months without further development. It may be that unduly retarded dentition will be the first circumstance to call attention to the probable character of the disturbance. As nutrition of the brain becomes more impaired nervous irritability increases, as evinced by constant fretfulness indicative

*Read before the American Orthopedic Association, 1894.

of suffering, restless tossing, especially of the arms, rolling the head from side to side, and loss of interest in surrounding objects. Convulsions are not uncommon. Some writers go so far as to say that rickets is by far the most common cause of infantile convulsions. This statement appears to me somewhat exaggerated. When they do occur they present the ordinary picture—fixation of eyes, pallor, rigidity, embarrassed respiration, with inversion of the thumbs and great toes—"carpopedal contraction." The tonic spasm known as tetany is of frequent occurrence. Less severe cerebral irritation may be manifested simply by twitching of the eyes and lids or of the facial muscles. These disturbances may continue for a few days or may persist at intervals for months. One of the most characteristic of the convulsive manifestations is that of spasm of the larynx, to which the name of laryngismus stridulus has been given, from the hoarse metallic tone produced by the rushing of the air through the tense glottis when the spasm begins to relax. This may occur in various degrees of severity, from a mere momentary holding of the breath to so prolonged a period of suffocation as to threaten, if not actually cause, death.

Implication of the vasomotor nerves is indicated about this time by enlargement of the arteries, already referred to, consecutive enlargement of the veins of the head and the neck, and profuse sweating of the head, especially during sleep.

To the same general cause may be assigned the bronchial catarrh, accompanied by cough, which passes under the name of chronic bronchitis, and often masks the true character of the disorder. Sensory disturbances of the nervous system may occur at almost any time. These manifest themselves as general hyperæsthesia, the flesh being sensitive to pressure at any point, or as tenderness in the joints, producing pain on motion. The child then shows the greatest disinclination to being moved, preferring to lie undisturbed upon the back, and caring little to be amused. Should he be old enough to walk he will gradually evince less and less desire for locomotion until he abandons the effort altogether. This has been explained by the fact that walking caused pain, or on the ground of general debility. My own belief is that there is an actual paresis in many cases, due simply to nerve starvation, and affecting more particularly the nerve fibrils distributed in the muscular tissue, in which the processes of metamorphosis and nutrition are to so great an extent carried on.

More or less closely following the manifestations referable to deficient nutrition of the nerve-tissue appear the trophic changes in the bones. One of the earliest is that known as cranio-tabes, consisting in defective and irregular development from the various centers of ossification in the skull, and perhaps even of absorption of bone cells. This is noticed in undue patency of the fontanelles and sutures and irregular depressions in the occipital region. The sensation conveyed to the examining finger is that of the existence of small oval hollows or soft spots in the occiput. The head is not usually large unless hydrocephalus be present, but is apt to be long, and the forehead is somewhat prominent and bulges laterally, like the prow of a Dutch lugger. Not only is dentition often delayed, but the teeth emerge more widely separated than usual, and are frequently notched as in inherited syphilis. It is in the long bones, however, that the more striking changes occur. These are enlargements of the epiphyses and softening of the shafts, the former due to excessive proliferation, the latter to loss of the mineral framework. The wrists and ankles become awkwardly large and bulbous, while the shafts yield to undue pressure or muscular contraction, thus producing curvatures in the limbs. Among the first of the long bones to afford indication of the changes going on are the ribs, which become enlarged at the sternal extremity, or "beaded," as the phrase is. To this succession of small prominences along either edge the French have given the somewhat fanciful name of the "rhachitic rosary." Curvation of the shafts may begin very early, especially in the tibia. While it progresses more rapidly under the pressure of the weight of the body if the patient is walking, yet it is easily recognizable in infants who have never attempted to stand.

The deformities caused by the rhachitic vice of nutrition are so varied that to describe them would open up the whole subject of orthopedics. Bow-legs, knock-knee, flat-foot, the various spinal deviations, pelvic irregularities and contrac-

tions, and thoracic distortions may all be traced to it. The deformity of the chest is characteristic. The clavicles (well named) lose their power to act as braces, their curves become exaggerated, the shoulders fall together, the sternum and, with it, the anterior extremities of the ribs are forced out, and chicken-breast is developed, often exaggerated at the base of the thorax by the abdominal distention already referred to.

Lateral curvature of the spine, although often resulting, is less frequently observed than posterior curvature, involving the entire spine, but most marked in the dorso lumbar region. In standing this curve is often apparently reversed, owing to obliquity of the pelvis and the necessities of equilibriation, producing a marked lordosis

The diagnosis of rickets is a matter of little difficulty when once the characteristic bone-changes have developed in any considerable degree, and it is in that stage that cases usually come under the observation of the orthopedist. But in the early months of the affection, when it is usually amenable to treatment, as hinted at the opening of the paper, it unquestionably often escapes recognition until irreparable injury has been done. Constantly compelled, as we are, to witness the life-long mortification and misery which attend the later manifestations, it would seem to be our duty to call the attention of family practitioners to the great importance of being on the watch for the earliest indications of the disease in artificially nourished infants. This affords one of the many fields opening for preventive medicine. The diagnostic marks have been sufficiently pointed out in the description of the manifestations of the affection.

As regards the *differential diagnosis*, attention has already been called to the fact that in its incipiency it is frequently treated for comparatively long periods as a gastro-enteric disorder, just as spinal caries has too often been, owing to the fact of its initial gastralgia. The practitioner may also be misled by the *quasi* chronic bronchitis.

Bradford and Lovett in an admirable *resume* of the subject in their *Treatise on Orthopedic Surgery*, say: "Rickets is so often the outcome of a long period of ill-health that it is difficult to say where the rhachitic symptoms begin." To this statement I take respectful exception. I believe the long period of ill-health which often precedes the characteristic lesions to be simply the initial stage and not the cause of the disease. It is the failure to recognize this initial stage which leads to the development of so much deformity. Any bottle-fed infant who suffers from constant indigestion and nervous irritability should be subjected to the most careful scrutiny. If profuse sweating of the head, abnormally large secretion of urine, copious phosphatic deposits in the urine, and hyperæsthesia are found to exist, it is quite unnecessary to wait for lesions of the osseous tissue to confirm the suspicion of the existence of rickets.

Rhachitis may be mistaken for Pott's disease, true lateral curvature, congenital syphilis, and acute rheumatism.

The first-mentioned affection is the only one which is likely to produce much confusion in the mind of the practitioner, and from that the discrimination is often extremely difficult when the excurvation is in the lower third of the spine.

In Pott's disease the rigidity is greater and more persistent, especially on first awaking from sleep; the paroxysms of pain are more acute, and in the intervals of pain the little sufferer is comparatively cheerful. There is not the history of traumatism in rickets which is almost always found in caries. There is often a peculiar transparent waxy pallor in the earlier stages of rickets which does not accompany the same stage of the tubercular disease.

Idiopathic lateral curvature rarely occurs at the early stage at which rickets appears, and the latter disease has set its unmistakable seal on other parts of the skeleton before the spine has begun to show serious indications of distortion.

Acute rheumatism is rare in infants, is acute in its course, and is usually accompanied by high fever. The periarticular swelling, with frequent red discoloration of that disease, is quite unlike the clubbing of the ends of the bones in that under discussion.

The absence of snuffles, sore throat and mucous-membrane and skin lesions serve to differentiate the latter from syphilis of the newborn, although there is some similarity in the bone changes.

Of the necessity for the exercise of the

utmost care in avoiding the error of confounding the early symptoms with those of simple bronchitis and gastro-enteric disturbances, and of the means of so doing, enough has been said above.

The *prognosis* of rhachitis is to be considered with reference first to fatal result, and secondly to the production of deformity.

The books usually make very light of the gravity of the affection as threatening life. It certainly figures very rarely in the mortality returns. I believe that this is due in part to failure to recognize the disease, and that very many cases which have the death certificate made out for acute pulmonary diseases, convulsions, or disorders of the digestive tracts, ought properly to be labelled "rickets." An affection which so profoundly affects the nutrition cannot be regarded as trifling. The diarrhœa of rhachitis will sometimes carry off its victim in a few hours with all the violence of *cholera infantum*, and the bronchial catarrh which has continued for weeks with little modification, may suddenly terminate in a fatal engorgement of the lungs. Too great vigilance cannot be exerted, therefore, for the detection of the disease at the earliest possible moment, inasmuch as the usual remedies for the other affections named, if not positively harmful, will at least have no beneficial effect on this deep-seated vice of assimilation.

Discovered in time, however, it is usually amenable to treatment, and in the very large majority of cases not only can life be saved, but serious deformity can be averted. It is often as surprising as it is gratifying to see what appropriate regimen and medication, unaided, will accomplish toward the correction of very marked distortions of rhachitic origin. Add to these the potent influence of massage over the nutritive processes, the mechanical redressment which can be effected by carefully regulated exercise, both passive and active, and our ability to control and correct processes of deformation by judiciously devised appliances, and the outlook becomes a very hopeful one. When once decided changes have shown themselves in the skeleton, even if distortion can be avoided, loss of stature will inevitably result.

In conclusion, I would call attention to the fact which I think I have observed, that rickets and its congener, scurvy in infancy, have within the past few years been decidedly on the increase. In point of fact, if one looks over the text-books on the diseases of children, written forty or fifty years ago, he will fail to find the slightest allusion to the last-named disease. And this, notwithstanding the fact that our fathers in medicine saw it twenty times in the adult where we see it once. Manifestly it was not for want of familiarity with its symptoms that they failed to recognize it as one of the infantile diseases. Indeed, we need hardly go back more than ten years to find medical literature barren of allusions to this subject. To what are we to attribute this somewhat sudden increase in diseases of defective nutrition. Is it simply a coincidence that this condition has developed simultaneously with and *pari passu* with the introduction of the practice of the sterilization of milk? One curious feature of this increased development of these affections is that we meet it not among the poor, not among those whose hygienic environment is faulty and whose food supply is insufficient or of inferior quality, but among the children of the wealthy, who live under the most favorable conditions, with strictest attention to hygienic precautions and an abundant supply of the richest milk.

Let us consider for a moment the part which ferments play in the preparation of food for digestion and assimilation. We know to how great an extent the digestibility of the great staple of life, bread, is increased by the development in the flour of the *saccharomyces cerevisiæ;* how beer in its various forms becomes a wholesome drink through the action of the same ferment; how the vinous fermentation furnishes both healthful beverages and useful stimuli; how the acetic fermentation supplies us a most valuable condiment. We also know that of all the ferments none approaches so near the fluid known as the gastric juice as lactic acid. We know what a wholesome and nutritious article of diet milk becomes in the shape of curds and whey, buttermilk, cheese, and matzoon, after having been acted on by the lactic-acid ferment. We know that under all ordinary conditions milk contains the lactic-acid bacterium. Now, is not the supposition warranted that, up to the point when this ferment has been devel-

oped in milk to such an extent as to produce an acid taste, which leads most persons to dislike it, its action on that fluid may be in the highest degree favorable to its digestibility and assimilability? Moreover, may not the lactic acid have a very important function in taking up the lime-salts, and in combination with phosphoric acid, putting them in condition to be absorbed by lacteals and appropriated by the system? The fact that sterilized milk is indigestible no one questions. May we not be denying our infants some of the most important of the constituents of milk, allowing them only the fats while we deprive them of the salts? To atone for presenting them a less-digestible milk we pre-digest it, thus depriving the stomach of the natural stimulus afforded by the presence of food requiring digestion, discouraging the secretion of the gastric juice, and still further interfering with the assimilation of the mineral constituents. Do we not perhaps need to revise our recent conclusions on the subject of infant diet and sterilization of milk?

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

TREATMENT OF FRESH WOUNDS.

Dr. Wechselmann (*Medicinische Neuigkeiten*, No. 45, 1894) warns the general practitioner against the use of the multitude of new antiseptics which have recently been thrown upon the market, for they are of doubtful value and dear. The bichloride, carbolic acid and iodoform are the standard antiseptics. Besides these absorbent cotton, sterilized mull, iodoform gauze, pure soda, potash soap sublimated silk and bandages are the requisites for the surgical bag. The chief duty of the physician in fresh wounds is the prevention of infection. The first important feature is the disinfection of his own hands. Here Fuerbringer's advice is applicable: washing the hands for one minute, with a brush, potash soap and warm water, then follow for one minute with alcohol and finally, for one minute, washing with a bichloride solution, 1:1000. The brush should be kept continuously in a 1:1000 solution of the bichloride or be frequently boiled in a soda solution. It is more convenient to keep special brushes for suppurating wounds as well as special instruments also for this purpose: two scalpels, one dressing forcep, an artery forcep, a pair of shears and a director. They should be boiled for fifteen minutes after each time used in a solution of soda. A simple enameled kettle is quite sufficient. The instruments are merely placed in this vessel, enough water placed over them to cover them and about a tablespoonful of soda added for each quart of water and then it is placed on the stove. In ten to fifteen minutes while the other preparations are being made they will have been boiled sufficiently. The kettle and the instruments are then cooled by placing it in a larger vessel of cold water. In a the fresh wound one may proceed as follows: wound is first covered without having been previously touched, with a compress wet with a solution of the bichloride, 1:1000, the instruments sterilized as directed, the hands disinfected, the vicinity of the wound disinfected by washing with potash soap and water always away from the wound towards the periphery, if necessary shaving and then with a second washing with alcohol and the bichloride. The wound is then covered with a second compress, the hands again disinfected, the instruments then are taken out of the soda solution and placed into a clean dish (no antiseptic solution is necessary) and then the wound is attended to. In wounds that are greatly crushed or where asepsis is doubtful a place should be left open and slight drainage be made with a strip of iodoform gauze. The wound is then dusted with iodoform powder, covered with iodoform gauze and with absorbent

* In charge of the translator, F. H. Pritchard, M.D.

cotton and then over this a simple mull or starched gauze bandage. The first dressing should be renewed according to the size of the wound from the third to the fifth day when, at the same time the stitches and drainage may be partially or wholly removed. The second dressing should be removed if an uncomplicated course is expected at about the time that healing will have taken place, as too frequent and unnecessary changing of the dressing only hinders healing. After this a piece of cloth, spread with a boric acid salve, is quite sufficient. In suppurating or otherwise infected wounds dry dressings do not do as well as moist ones which are changed once a day or oftener. Here compress, wet with a 1:2000 or a salicylic acid solution, over which is placed gutta percha, paper, etc., will do good service. Beware here of a carbolic solution which frequently acts as a caustic and on the fingers gives rise to gangrene.

MERCURIAL TREATMENT OF TABES DORSALIS.

Dr. Shuster (*La Semaine Médicale*, No. 71, 1894) is an advocate of mercury in tabes dorsalis. It is contraindicated in those weakened by long duration of the disease, while in those still robust it will bring about a decided amelioration, and that not only where there is syphilitic history, but where the antecedents are negative on this point. It is best administered as the bichloride in pill form and in daily doses of one milligram, continued for a long time, and in connection with the following pill:

Arsenious acid.....	o	05	gr. ¾
Strychnine.....	o	10	" jss
Extr. and powdered licorice. ..	q	s.	

Sufficient for one hundred pills. One to two a day.

TREATMENT OF URTICARIA.

Dr. Brocq (*Revue Intérnationale de Medecine et de Chirurgie Pratigues*, No. 19, 1894) recommends, in the management of urticaria, the following measures:

Apply locally the following salve:

Carbolic acid.....			
Essence peppermint.....	ää 1	o	grs. xv
Oxyde zinc			
Lanoline.....	ää 20	o	3v
Pure vaseline.....	60	o	3ij

At the same time, prescribe each day from two to six of the following pills:

Muriate quinine.....			
Ergotine.....	ää o	10	grs. jss
Extr. belladonna.....	o 01–0	02	" ½–½

Before applying the ointment one may apply locally a lotion with vinegar, cologne water or chloral as a base.

CHLORATE OF SODA AS A REMEDY.

Dr. Barrat (*La Medicine Moderne*, No. 8, 1894) has found the chlorate of soda less toxic and more soluble than the corresponding potash salt. He has given it in two cases of cancer of the stomach, in doses of ten grams (3ijss) a day, in one of which he claims a successful result (?). In a case of epithelioma of the upper lip he injected a cubic centimetre (gtts. xv) every two days into several points of the tumor. The result was successful for healing followed.

DISAGREEABLE A TION OF THE DIPHTHERIA ANTITOXINE.

Dr. V. Cnvrim (*Deutsche Medicinische Wochenschrift*, No. 48, 1894) injected a fellow practitioner for a diphtheritic attack with ten ccms. of Hoechster serum, No. 2, respectively, No. 3. The disease soon disappeared. In six days an urticaria like exanthem appeared on the thigh at the place of injection, followed in the next few days by enlargement of the neighboring glands, pains in the elbow and knee joints, muscular pains with hammering headache and a rise of temperature to 39.5° C. In ten days from the time when first injected the symptoms began to decrease. Dr. K. was also attacked with similar symptoms after injection of 10 ccms. of serum No. 1. Here the general symptoms appeared after four days, the first glandular involvement after seven days, as in the former case at an angle of the jaw, and urticaria appeared on the eighth day. From the eleventh day the symptoms began to abate. Even twenty-one days after he experienced pains in his right arm and had difficulty in using it.

LOCAL TREATMENT OF DIPHTHERIA.

Dr. Ignatovsky (*La Semaine Médicale*, No. 67, 1894) speaks highly of the following as quite efficient in the local treatment of diphtheria:

Essence of peppermint	8	o	3 ij
Essence of turpentine.....			
Petroleum, ää.....	30	o	3 j

Apply locally on a swab every one to two hours.

HOW AND WHEN TO GIVE DIGITALIS.

Professor Huchard (*Médicine Moderne*, No. 9, 1894) protests against the tendency of physicians to wait in asystolia until the disease has reached its final stage. On the contrary, one must act energetically from the very beginning. The three capital indications for the use of digitalis are:

1. Weakening of the contractile force of the heart.
2. Lowering of arterial with heightening of venous tension.
3. Scanty urine with peripheral œdema and visceral congestions.

One should not wait until these congestions have set in, but give the remedy as soon as perimalleolar or peritibial œdema is noticed in the evening. Before administering it he would have his patient rest in bed and put him on partial or absolute milk diet for several days. The second or third day he would administer a purgative consisting of 60 cgms. (grs. ix) of calomel and resin of scammony in two powders. The following day he prescribes 40 to 50 drops of a 1-100 solution of crystalized digitaline, *i.e.*, 1 mgms. of the amorphous variety. The next day its effects will be remarked and the quantity of urine will be increased.

TREATMENT OF THREATENING AND INEVITABLE ABORTION.

Dr. C. Marocco (*Le Semaine Médicale*, No. 67, 1894), in cases of unavoidable abortion, advises tamponing the vagina with gauze soaked in glycerine and administering internally one of the following powders:

Phenacetine.....	0 | 30	grs. v
Muriate morphine.....	0 | 01	grs. 1-6

Sufficient for one powder. Make three such. One each hour.

Under the influence of this treatment the abortion will terminate almost without pain in twenty-four hours.

COMPARATIVE VALUE OF THE DIFFERENT PREPARATIONS OF IRON IN ANEMIA.

Dr. Herschell (*Medicinische Neuigkeiten* No. 49, 1894) has experimented on sixty-five polyclinic patients with regard to the comparative therapeutic value of the various preparations of iron in anemia and he has obtained results which deserve to be known. As a means of determining he employed Fleischl's hæmometer before beginning and on the twentieth day of treatment. His results were as follows:

Blaud's pills gave an average daily increase of 1.2 per cent. (tabloids).
Blaud's pills gave an average daily increase of 0.5 per cent. (ordinary pills).
Sulphate of iron gave an average daily increase of 0.5 per cent
Chlorate of iron gave an average daily increase of 0.5 per cent.
Citrate of iron gave an average daily increase of 0.5 per cent.
Albuminate of iron gave an average daily increase of 0.125 per cent.
Dialyzed iron gave an average daily increase of 0.125 per cent.

These results are in striking contrast with those claimed to have been obtained with the different albuminates sold by the various manufacturers. This may be explained by the fact that the carbonate of iron is most active in statu nascendi, *i.e.*, when formed in the stomach by the mutual action of the sulphate of iron and the carbonate of potash upon each other as takes place with Blaud's pills. With the albuminates, peptonates and colloid preparations a deposit of the insoluble carbonate is formed in the stomach when coming in contact with the hydrochloric acid. Hence the old method of prescribing iron is still the best.

POISONING BY A THERAPEUTIC DOSE OF CREASOTE.

Dr. Zanadski (*Wiener Medizinische Presse* No. 51, 1894) reports the case of a women who within twenty-four hours took six drops of creasote, three times, in milk. Soon symptoms of intense disturbance of the stomach and intestines followed accompanied by anesthesia and paresis of the velum palati and of the vocal cords; besides she presented traces of its caustic action on the mucous membrane of the mouth and throat, albuminuria and signs of heart weakness; the breath smelled strongly of creasote. Death followed after a week. The necropsy revealed numerous bloody suffusions of the stomach and intestines, a few ulcerations of the œsophagus and pyloric end of the stomach, degeneration of the liver, acute nephritis and hyperemia of the brain. He explains this unfortunate result by the fact that creasote is insoluble in milk and acts as if undiluted and to a peculiar idiosyncrasy. He therefore recommends beginning with small doses, one to two drops, and only gradually increasing the dose.

POISONING BY GLYCERINE AS A VEHICLE FOR IODOFORM

Dr. Schellenberg (*Hospitals Tidende* No. 51, 1894) would reject entirely the use of glycerine as a vehicle for iodoform in its local use, as it is capable of giving rise of decidedly disagreeable or even fatal results. He would at least advise great caution in employing it on extensive wound surfaces or in large cavities. He would regard ten ccms. as the largest quantity to be used at one time in children and twenty to twenty-five ccms. in adults. Glycerine is capable of provoking all degrees of renal irritation from reddish discoloration of the urine, with presence of red blood corpuscles and casts, to a state of collapse with uremia and death.

LEMON JUICE AS A HEMOSTATIC.

Dr. E. T. Burton (*Wiener Medizinische Presse*, No. 49, 1894) speaks highly of the use of lemon juice as a hemostatic. In a severe case of epistaxis, in a plethoric young man with copious hemorrhage from both nostrils, after injection of a solution of lemon juice and water (1:4) into the nose with an ordinary glass syringe the hemorrhage ceased. In a case of hematemesis in a woman of thirty years, in whom all the usual remedies had failed the hemorrhage ceased at once after employment of pure lemon juice. It returned, however, the next day but was rapidly controlled by the use of this simple remedy so that she rapidly convalesced. In a case of intestinal hemorrhage, in typhoid fever, it was also given with equally favorable results, for it ceased as if by magic. The patient died, however, from exhaustion. In the last two cases there was violent vomiting and everything except the lemon juice was ejected.

HEART DISEASE AFTER THE GRIPPE.

Dr. Sansom (*Hospitals Tidende*, No. 50, 1894) finds that some of these cases require nothing beyond a regulation of the hygiene as they present no symptoms. As a rule the patient suffers more or less and the physician may be called during a dyspeptic attack or a "vagus storm," as he calls it. These are best treated by bismuth and alkalies or together with small doses of arsenic. During the painful crises morphine subcutaneously is occasionally necessary though opium, as a rule, is not tolerated. Phenacetine is an excellent remedy in controlling the pain; chloralamid is of service in the sleeplessness, sulphonal is by no means harmless and chloral and the opiates are injurious. In the treatment of arhythmia digitalis is harmful and all other heart remedies excepting belladonna are inactive; this latter, in some cases, has given him good results. Though the action is not so striking as in tachycardia yet a beneficial result will be obtained by application of the galvanic current to the pneumogastrics. It may be applied for six minutes, three times a day, but it must be quite weak. At least six months are necessary before marked improvement is noticed.

COCAINE TO STOP THE SECRETION OF MILK.

Dr. E. Casoli (*Norsk Magazin for Lægevidenskaben*, No. 12, 1894) in a woman whose child died soon after its birth and who was troubled with a profuse secretion of milk, ordered her apply to both breasts, twice a day, a five per cent. solution of cocaine. In one day the secretion was greatly diminished and in two days it had ceased entirely.

TREATMENT OF POST-PARTUM HEMORRHAGE.

Professor Leopold (*Lo Sperimentale*, No. 35) says that if one be called to a woman who is losing blood, on account of the difficulty of ascertaining promptly the cause of hemorrhage one should proceed to examine systematically. The bladder should be first emptied; then it should be seen if the uterus is contracted; if this be so, then the hemorrhage comes from the vagina, the cervix or the lacerated clitoris. If examination of the placenta shows a piece to be lacking, it should be sought for and extracted. As to the membranes the treatment differs, for only those in the vagina or cervix are to be removed. Cervical lacerations should be looked for and treated. If this is impossible, tamponing is the next best measure which, however, has its disadvantages on account of one being obliged frequently to employ material which is far from aseptic. Tamponing the vagina alone is not sufficient as the hemorrhage is liable to continue into the uterus. In extensive

laceration of the cervix, introduction of the hand into the vagina and manual compression of the lips of the collum with the hand, if continued for ten minutes or longer, will suffice in some cases. On the contrary, the cervix may be drawn down and the laceration be sutured. Tamponade of the lower segment of the uterus will sometimes suffice when this fails. He thinks that post-partum hemorrhage is often due to too rapid expulsion of the placenta by the physician. Tamponade is especially indicated in atonic hemorrhages.

TREATMENT OF NEPHRITIS WITH THE WET PACK AND PILOCARPINE EXTERNALLY.

Dr. H. Mollière (*Wiener Medicinische Presse*, No. 49, 1894) warmly advocates the use of the wet pack and pilocarpine in the treatment of nephritis. The latter remedy is employed as a salve of the following constituency:

Nitrate pilocarpine....0.05–0	10	(gr. ¾–jss.)
White vaseline 100	0	(℥ij ℥j.)

The whole trunk is rubbed with this salve. Large doses of the drug will cause disagreeable skin eruptions which will render interruption of treatment necessary. After inunction a layer of cotton batten is applied, over this some impermeable material and the whole fixed by a bandage. The dressing is only changed when it is completely saturated with sweat; it may be renewed after several hours. The results were the same in patients with and without milk diet and consisted in a rapid recovery in acute and immediate improvement in chronic cases. In these latter the result might extend over several years. He has treated thus at least fifty cases, and in all except in those where there were signs of extensive destruction of renal parenchyma the results were quite satisfactory. The advantages of his method he claims are in the sudorific properties of pilocarpine and the increased diuretic action which is the more efficacious as it takes place through the nervous system and not through an action on the kidneys. The action of the drug seems to be purely local for none could be detected in the urine. He thinks his method of especial value during convalescence when the patient is tired of milk diet and returns to an ordinary diet.

GUAIACOL IN TONSILLITIS.

Dr. E. Darbouet (*La Semaine Medicale*, No. 70, 1894) is quite enthusiastic over the results which he has obtained with guaiacol in the treatment of tonsillitis. He would not advise its use pure as it is too irritating, but mixes it with equal parts of glycerine; in children in proportion of one to two. He applies it locally on a swab four times in twenty-four hours, late at night before going to bed and early in the morning. Thus the patient will pass a comfortable night. The first sensation is disagreeable but this soon disappears and, in a moment, the patient finds to his astonishment he can easily swallow. The painfulness returns, but is well under control of the remedy.

Methol in Diptheria.

F. Kastorsky (*Brit. Med. Jour.* reports thirty-seven cases of diphtheria (in three adults and thirty-four children) treated and cured by painting with a ten per cent. alcoholic solution of menthol. The paintings (by means of a piece of cotton wool) were usually carried out three times daily. In some cases, however, a single free application was followed by complete disappearance of false membranes within two days. A marked improvement in the patient's general condition was invariably noticed from the beginning of the treatment. The same simple method was successfully practiced by the author in numerous cases of anginas of various forms, and by Trütovsky in a group of cases of scarlatinal diphtheria.

A New Method of Disinfecting the Mouth and Throat.

Experimenting with colored fluids, the author found that only the soft palate and tongue came in contact with the solution used, and consequently they are without value. He recommends the use of bonbons made from saccharine and resin guaiaci, and claims that in their use the entire mucous membrane of the mouth and throat is brought into contact with the disinfectant used. Their value is proven in that the bacteriological examination of the secretion of the mouth shows it to be free from bacteria after the use of the bonbons, when they had been present before.—*Szanas in Archiv. fur Kinderheikunde, Arch of Pediatrics.*

BACTERIOLOGICAL NOTES.

BACTERICIDAL POWER OF DOG'S BLOOD AND ITS RICHNESS IN LEUCOCYTES.

Much has been written upon the bactericidal power of the blood of different animals. The practical outcome of this work is being manifested at present in the use of serum in the treatment of diphtheria. In view of the importance which often attaches to the results of apparently insignificant experiments, the results of such work as Havet has recorded (*La Cellule*, x (1894) p. 221) should not be overlooked. Havet has carried on experiments with dogs for the purpose of testing the germicidal effect of serum. He finds that the white blood corpuscles almost or altogether disappear when microbic products are injected into the blood, and this disappearance is coincident with partial or total loss of bactericidal power. As the leucocytes reappear the bactericidal power of the serum returns *pari passu*. When living cultures are injected into the tissues, the stage of hypoleucocytosis is accompanied by a diminution of the bactericidal power and conversely, hyperleucocytosis by increase. This increase is due to the presence of leucocytes in greater numbers, and is not the result of some newly acquired property of the serum. No fixed relationship between richness in leucocytes and bactericidal power can be established, for the leucocytes may be weakened either by a previous digestion of microbes, or by microbic poison. Leucocytes, in case of two kinds of organisms, may incorporate both or only one.

DIFFERENCES BETWEEN BACTERIUM COLI COMMUNE AND BACILLUS TYPHOSUS.

Fremlin (*Archiv f. Hygiene* xix, p. 295) enters into a long discussion of the differences existing between these two species of bacteria. He has compared the morphological, cultural and pathogenic properties of these two species. He used cultures of *B coli* obtained from man and several of the lower animals. He found that *B coli* presented two appearances on gelatin, viz., membraniform film and points. He finds that there are distinct differences between the two organisms. *B typhosus* is more motile, and possesses several flagella which are easily stained. *B coli* has only one flagellum which is stained with difficulty. *B coli* gives the indol reaction—*B typhosus* does not. The latter has a great tendency to form filaments by the connection of several individuals. *B coli* forms more rapidly on agar and gelatin than the typhoid bacillus.

[Since Rovet and Roux published the results of their investigation in which they advanced the idea that these two bacteria were identical, the REPORTER has endeavored to give a *resumé* of the work done on these two organisms to affirm or refute their conclusions. The importance of positively identifying these forms render the consideration of all facts bearing upon this point unusually interesting. The statement of Fremlin in reference to the morphology of the two organisms has been shown to differ from the results stated. Moore found that the flagella stained quite as easily in one species as the other. He also found that the number were nearly as great. More recently Bunge (*Fortschrette der Med.*, Nov., 1894) confirms Moore's results. The difference in the gas producing power of this organism as determined by Smith is also omitted. It is interesting to note, however, the difference in the tendencies between the French and German investigators in reference to the identity of the two organisms.—ED.]

THE MORPHOLOGY OF BACTERIA WITH SPECIAL REFERENCE TO THE BACILLI OF ANTHRAX, TUBERCULOSIS AND DIPHTHERIA.

The investigations that are being made with reference to the identity of the bacillus of typhoid fever and *bacillus coli* renders all work bearing upon the morphology and especially the polytypes of pathogenic bacteria a matter of considerable interest. Recently Klein (*The Quarterly Journal of Microscopical Science*, 1894, vol. 36) has published the results of his observations on the morphology of the three species of bacteria in question, from which he concludes that they are not typical bacilli as they are usually represented to be. He finds that while under many conditions their morphological characters are those of typical bacilli, under other conditions they are not, but revert to or assume forms indicating their relationship to saccharomyces or to still higher mycelial fungi. With regard to the bacillus of diphtheria the author points out that the club-shaped expansions of one or both ends are not to be regarded as due to involution, for both under natural and artificial conditions where there is active growth, these expansions will be found, and have moreover, a striking resemblance to the ends of growing hyphæ. Their existence therefore is to be explained by their representing a relationship to a mycelial fungus. For the other two species he shows in a somewhat similar way their relation to higher fungi.

[The fact is well known that many eminent bacteriologists consider certain pathogenic bacteria to have sprung from forms not supposed to be pathogenic, but the conclusions of Klein in which he attributes the most characteristic morphological characters of these bacteria to analistic stages found in higher fungi will undoubtedly meet with much adverse criticism.—Ed.]

NEW METHOD FOR STAINING TUBERCLE BACILLI.

Leutelle (*Bull.-Soc. Belged de Mic.*, xx, p. 184) recommends a somewhat new process for staining tubercle bacilli in any condition of tissue or in cover-glass preparations. The preparations are to be immersed for one to twenty-four hours in carbol-rubin and then transferred to a 1.5 per cent. solution of permanganate of potash. This is followed by immersion in a saturated, aqueous, freshly prepared solution of sulphuric acid. The preparations are then washed in water, after which they may, if desired, be double-stained with saturated aqueous solution of methylineblue. In this case the sections are washed, dehydrated in alcohol, cleared in xylol and mounted in balsam.

STAINING MICRO-ORGANISMS IN THE BLOOD.

Vincint (*Gaz. Med. de Paris*, 1894, p. 296) recommends the following method for staining micro-organisms in the blood. The cover-glass preparation is prepared in the usual manner. After which it is treated for 1 to 2 minutes in the appended solution: 5 per cent. carbolic acid 6 cc.; saturated salt solution 30 cc.; glycerine 30 cc; the solution is to be filtered before using. This fluid dissolves the hæmaglobin, does not alter the shape of the red corpuscles and causes no precipitate. The fluid is drained off, the preparation washed in water, is counter-stained in carbol-methyline-blue plus ½ per cent. aqueous methyl-violet solution. This method is mentioned as a good process for demonstrating the malarial plasmodia.

THE DEMONSTRATION OF INFLUENZA BACILLI.

Borchardt (*Berlin Klin. Wochenschrift*, No. 2, 1894) records his experience with Pfeiffer's influenza bacillus which he found in thirty-five out of fifty cases examined. He lays much stress on the observance of the method used by Pfeiffer. The bacilli are demonstrated in the sputum which must be fresh and washed with sterile water. Cover-glass preparations are then made from the central portions of the lumps of sputa and stained with carbol-fuchsin 1 to 10, after which they are washed in water or decolorized in dilute acetic acid. The bacilli are observed free and often in pure preparations but usually other bacteria are present. The influenza bacilli sometimes appeared within the cells, and again in little clumps or swarms.

The influenza bacilli may be demonstrated in the sputum for at least a week during the course of the disease. As they do not react constantly to staining reagents the microscopical examination does not always succeed, especially when from polar staining they resemble diplococci. Cultivations are sometimes unsatisfactory. Cultures are best made by washing a mass of sputum in sterile water and placing it in a tube of bouillon and throughly mixed, from which tubes of inclined agar or agar containing blood can be inoculated. Although these cultures are impure usually, the influenza bacilli form small, clear, homogeneous, structureless colonies by which they can as readily be distingushed from those of the other bacteria.

CORRESPONDENCE.

CIRCUMCISION.

EDITOR MEDICAL AND SURGICAL REPORTER:

DEAR SIR: I notice in THE REPORTER of February 9, 1895, page 218, an editorial on Circumcision, which you reprint from the *Medical Record*. To allow this editorial to go unchallenged would be doing mankind in general a great injustice, unless its author wishes to confine his remarks to a very much shortened and retractable prepuce.

Circumcision may be a relic of barbarbous and semi-civilized times, but we cannot deny it many advantages.

The removal of the prepuce serves as many useful purposes at the present time, as it did among the nomadic tribes of tropical countries. We have no assurance when a child is born that its habits will be sanitary to any degree whatever.

It is a fact that syphilis and gonorrhea are less prevalent among men who do not have prepuces than those who possess them.

Any man in the practice of medicine should know that it is not necessary to remove the prepuce if it does not cover more than one-third of the glands and can be retracted with ease beyond the corona, unless it should be eczematous or otherwise diseased.

A personal experience with two hundred and twenty-five circumcisions leads me to say that it is one of the most valuable of operations, and that I would, without hesitation, advise its general adoption.

I am very truly,

MERRILL RICKETTS.

Cincinnati, O., Feb. 14, 1895.

EDITOR MEDICAL AND SURGICAL REPORTER.

DEAR DOCTOR; I should be greatly obliged for any information that may be sent me personally or through your columns, regarding the efficacy to the salol and potassium iodid tests for gastric motility and absorption, respectively. Information is particularly desired with regard to cancer, ulcer and other serious troubles. Due credit will be given for any such information, providing the results of my study are published.

Very truly yours,

A. L. BENEDICT.

174 Franklin St.,
Buffalo, Feb. 12, 1895.

EDITORIAL.

AN OVERCROWDED PROFESSION—THE DEMAND FOR PHYSICIANS.

Last week we considered the medical profession and the opportunities of its members from the purely business standpoint of demand and supply. In this issue, we purpose to discuss in greater detail the demand.

The student of medical history is struck with this important difference between the physicians of almost all the nations of antiquity and of the middle ages, and those of our own century. The former, though, on the whole, occupying a lower social level, seem to have been less dependent on their practice, and, in their purely medical capacity, appear to have exercised a greater influence on their patients. A slave, a half-educated priest, an itinerant quack, attained reputations unknown in our days, received large fees, and were sought after by such crowds of people as, in these degenerate times, even the free dispensaries fail to attract. It may be that the accounts of the past are exaggerated, that the fortunate ones of whom we read were the exceptions; at any rate, we know that the attainment of even the moderate success which is possible in modern times, is an extremely difficult matter.

What are the sources of the demand for a profession to minister to the sick; and has there been any material change in this demand during recent times?

With the development of an highly artificial state of living, sickness increases up to that time when the need of exercise and the systematic attention to such various sanitary details as sewerage, plumbing, heating and ventilation, cleaning of streets and removal of garbage, is recognized. Within the last ten years, a tremendous advance has been made along these lines. Physical culture (using the word in no limited sense) has become fashionable. The free use of intoxicants, of tobacco and similar articles, the overindulgence of any of the appetites are frowned down by the very classes of so-

ciety which formerly fostered these vices. There has been a great increase in the spread of popular knowledge within recent years, and public sentiment now demands attention to hygienic details which would have been ridiculed or denounced as an infringement of individual rights, a decade ago. We are just at the beginning of the municipal use of expert bacteriological and chemical skill for the preventing of disease; yet the diminution already apparent, is great. Twenty years ago, small-pox was a not uncommon occurrence in general practice. Now, there are thousands of well-educated and experienced physicians who have never seen a case. Diphtheria, scarlet fever, cerebro-spinal meningitis were epidemic, almost endemic in many cities where they are now seen in scattered cases throughout certain months of the year. All these facts, gratifying as they may be to every right thinking physician, indicate a lessened demand for his services. Wholesale medicine has supplanted the retail efforts of the family doctor in the domain of sanitary science.

Children are born into the world, and the sentiment in favor of the obstetrician as against the midwife, professional or amateur, is growing. But it is noticeable in every highly civilized country that well-to-do families are producing fewer children; the births predominating among that class of the community which depends upon medical charity.

It is unnecessary to more than allude to the medical pauperizing of a large class of a community, particularly in cities, by hospitals, dispensaries and the like. The evil has not been exaggerated, and we can add but one new thought on the subject; namely, that the growth of such institutions is not only the cause of a relative poverty of medical men, but is the result of the overcrowding which drives physicians to expend their superfluous energy in charity work, with the hope that the experience or prestige of such occupation may lead ultimately to something better. Surgery in general practice has been almost wiped out of existence by emergency hospitals. Indeed, if a man of means fell unconscious within a block of his own home, the chances are that he would be conveyed to a hospital miles away before his friends could learn of his misfortune. Railroad companies are awakening to the fact that they can get a good share of their surgical service for nothing, and many have already contracted with emergency hospitals at rates which are only a fraction of what they willing paid years ago. Medical charity is thrust in the face of the community and, with increasing expense of living in cities, it is only the most honorable who will pay for medical service.

The diminution of infectious diseases, the inroads of free institutions, the observance of sanitary laws, the increase of poverty, all tend to lessen the demand for physicians' services. We should consider it a fair estimate to say that a ratio of one doctor to six hundred of the population now would be about equivalent to one to four hundred ten years ago. In other words, there should be no greater annual addition to the ranks of the profession now than when the population of the country was considerably smaller. This statement naturally leads to the consideration of the supply of physicians by medical schools, a subject which must be passed over at present.

It would seem that the demand for medical men might be increased by extending the domain of the medical profession. Graduates in law, for example, include real estate dealers, business men of all kinds and politicians beside the judicial and pleading branches of the legal profession proper. To a certain extent, the creation of boards of health, the appointment of municipal and state bacteriologists, chemists, etc., the

maintainance of insane asylums, almshouses, etc., do open new fields of usefulness to our profession, but, as a rule, medical men acting in the capacity of public servants are not well compensated, especially when comparison is made with the purely political office holders; and as has already been intimated, one man acting with the support of public office, indirectly removes the necessity of ten general practitioners.

We are not to be included in the category of those mercenary physicians who lament the occurrence of "healthy weather," or who complain, as one old man did to us some years ago, that "there has not been an epidemic for a long time." It is a great blessing that the earnest efforts of the profession for preventive medicine are beginning to bear fruit. There will always be a need not only for sanitary and hygienic advisors, but for an actual ministering profession. We need have no fear of the abolition of medical practice, but we must recognize the fact that fewer men will do the work of the coming generation, or else the remuneration of the average physician must suffer such diminution that he will be reduced to poverty if he has no means outside of his professional earnings.

ABSTRACTS.

THE DOCTORS OF NEW YORK REGIMENTS IN BROOKLYN.

It is always a hardship for men to be taken away from their business for the purpose of doing military or jury duty, and the service required during the recent strike in Brooklyn of a large part of the National Guard resident in the city of New York was an unusual hardship, for the weather was uncommonly trying, the men were badly housed and fed, a great share of what they did was in the line of police duty rather than military service, and they were almost constantly exposed to the missiles of concealed foes. Yet there was next to nothing from them in the way of complaint, even in private. They did there work manfully, indeed heroically.

Among these men there were members of our pofession, men who could ill afford the interruption of their practice that had to be submitted to. People are notoriously impatient and unreasonable when anything interferes with their obtaining their own doctor's attendance without delay, and we can well imagine the unamiable and captious remarks that must have been made in many a family during the week that a number of New York doctors were obliged to stay in Brooklyn. Moreover, there must have been in many instances a serious break in the continuity of a line of treatment that had been laid out. The doctors that we have in mind were not only the medical officers of the various commands, but also a very considerable number of physicians in the ranks. This was fortunate for the efficient prosecution of the medical service, for the regiments were for the most part in scattered detachments, and the medical privates were available for detail to medical duty. A number of doctors were thus made more useful than they could have been had they remained in the ranks, but that fact did not abate the chagrin they must have felt at an unnecessary sacrifice of their own interests. But there was no complaint on the part of these doctors, whether regimental officers or privates. They all did their duty faithfully, efficiently, and cheerfully, and they are deserving of the highest praise. The National Guard is certainly to be congratulated on the character of its medical men.

A NEW TREATMENT FOR TUBERCULOSIS.

For many months Dr. Paul Paquin, of St. Louis, has been experimenting with a remedy for tuberculosis. His conclusions were recently presented to the St. Louis Medical Society in a demonstrative manner. There can be but little doubt that Dr. Paquin has discovered nature's own treatment for tuberculosis. It is, perhaps, not saying to much to state that he has discovered a cure for that dreadful list of maladies to which the name tubercular has been applied. He employs the serum therapy, using the serum of the horse, an animal which rarely, if ever, contracts tuberculosis. In a large number of patients in the city hospital and poor house, upon whom the new treatment was tried, a gain in weight, a diminution and cessation of expectoration, a fall in temperature and, in fact, an amelioration of all symptoms was obtained.

Dr. Paquin presented the clinical histories of twenty-two cases treated with almost uninterrupted improvement. Nearly every case had gained in weight. Cough had entirely disappeared in patients with large cavities. The serum is obtained from horses rendered strongly refractory to the germ of tuberculosis by laborious processes. A remarkable feature in the result of the treatment was that not one of the seven cases which Dr. Paquin presented to the society coughed once during the entire evening. This, too, was after exposure to a cold wind on a very bad night. Dr. Paquin did not present conclusions with regard to his experiments, but expressed the opinion that the immunized horse-serum would soon be the natural agent to prevent and treat tuberculosis. He said that it was obviously too early to reach reliable conclusions, although the results seemed sufficient to justify the hope that the serum would arrest tuberculosis.

The results obtained by Dr. Paquin were confirmed by Dr. George W. Cale, a skilled bacteriologist and able surgeon. Dr. Cale believes that in the serun therapy we have a remedy of the greatest importance for bone and joint tuberculosis.

The preparation of the serum is expensive and requires minute attention to details. The filtration of the serum is a matter of the greatest importance, and in this Dr. Paquin was assisted by Dr. Given Campbell, who discovered a method of filtration superior to any heretofore in use.

It is worthy of note that the three gentlemen whose names have been mentioned above are young men, exponents of that scientific school of medicine of which Pasteur, Koch, Kitasato, Roux and Behring are leaders. It should also be remarked that they are ethical gentlemen who are not seeking notoriety. Unlike many of the older men of St. Louis, particularly the surgeons, they are peaceful citizens.—*Ed. Med. Fortnightly.*

DIPHTHERIA ANTITOXIN—SERUM THERAPY IN DIPHTHERIA.

The most interesting and important contribution to the recent Congress at Budapest was the report of M. Roux upon the serum therapy of diphtheria. The investigations cover a period of over three years and were carried on at the Pasteur Institute and the Hôpital des Enfants-Malades, with the assistance of MM. Martin and Chaillou.

BACTERIOLOGICAL AND EXPERIMENTAL WORK ON ANIMALS.

The process of obtaining an antitoxic serum is briefly this: by prolonged cultivation of virulent diphtheria bacilli in a specially prepared bouillon at a temperature of 37° C., with exposure to sterile air, a concentrated toxin is obtained in about three weeks, of such a strength that one-tenth of a cubic centimeter will kill a 500 gm. guinea-pig in forty-eight hours. After filtration this toxin is kept in tightly closed flasks away from the light. For the purpose of immunization this toxin is diluted with one-third of its volume of Gram's solution. While immunization was obtained in several species of animals, the horse was chosen as furnishing a

larger amount of serum with greater ease, and one which of itself causes the least disturbance when injected into other animals. By injecting repeated and gradually increased doses of the toxin, a horse is rendered immune, that is, able to receive 250 c.c. of pure toxin without disturbance, in two months and twenty days.

The serum from such an animal when added to the diphtheria toxin makes it inoffensive, and the mixture injected into animals causes no disturbance even of a local nature. The mixture may be made equally well in the animal's system. The serum, whether given before, with, or after the injection of the toxin, enables an animal to endure an otherwise absolutely fatal dose of toxin. It appears from experiments which we cannot here detail that the protective influence of the serum is not exercised by destroying the toxin but by stimulating or in some way affecting the tissue-cells so that they do not respond to the poison. If the tissues have been vitiated, as by the toxin of the streptococcus, they are not responsive to the serum, and the action of the diphtheria toxin is only delayed. The dose of the serum varies with the weight of the animal, the doses of the toxin and the relative time of administration.

Most of the experiments with serum were made under the skin, but a considerable series were made upon the mucous membranes, which were of especial interest for the clinician, as they gave an opportunity to study the action of the serum on the diphtheria of an external surface. Diphtheria was caused in female guinea-pigs by excoriating the mucous surfaces of the vulvæ and thereafter rubbing them with the pure culture of diphtheria bacilli. The character of the inflammation and the structure of the membrane thus caused is in every way similar to that in children. The guinea-pigs, who otherwise invariably died, recovered without exception if the serum was injected in a sufficient dose before the inoculation of the mucous membrane. In all these cases a false membrane is formed, but the redness is less extensive, the tissues less swollen and the fever less intense. After the second day the local lesions diminish, the false membranes become detached and repair sets in. Guinea-pigs of equal weight with the same virus, but not treated with the serum, died in six days. The protected animals received one-ten-thousandth of their weight of serum. The result was in every case the same if the serum was injected at the same time with the inoculation of toxin.

In a second series of cases the serum was injected after inoculation; the false membrane had already been developed for about twelve hours; the redness and swelling were very marked. If at this time the serum is injected in a dose of from one to ten thousandths of the weight of the animal, it recovers without exception. In a few hours the edema ceases, and on the second day the false membrane becomes detached. After the repair of the mucous membrane no diphtheria bacilli were found. The rapidity with which the false membranes were cast off was remarkable. Unprotected animals died on the fifth or sixth day.

The third series of cases was undertaken upon guinea-pigs and rabbits inoculated in the trachea. The guinea-pigs thus treated died, usually in three days, if not protected. The pathological appearances were in every way similar to those in children. When inoculated in the trachea after having received the serum treatment, they did not take diphtheria. If the quantity of serum was not sufficient the disease, however, made its disappearance after a short delay. The animals injected with toxin after serum treatment gave no evidence at all of the disease.

In cases of diphtheria associated with streptococci infection the serum only rarely brought about a cure; not that there was a larger amount of diphtheria toxin or that the antitoxic power of the serum was annulled, but because the cells depressed by the poison of the streptococci no longer responded to the stimulation of the serum. No better results were obtained in treating animals previously vaccinated against the streptococci; possibly the serum of the rabbits was not sufficiently effective against the variety of streptococci which was used.

CLINICAL OBSERVATION AND RESULTS IN CHILDREN.

After this long and careful experimentation the authors were prepared to apply their results to the treatment of diphtheria in children, which was done in the diphtheria ward of the Hôpital des En-

fants Malades. Treatment was begun on the first of February, 1894, and continued until July 24th, thus covering the winter months in which diphtheria is the most prevalent and severe, and the summer period when the disease is notably rare. The wards were visited each day, and all children found there were treated, whatever their condition. No discrimination was made, so that the results of several months' treatment could be fairly compared with previous times. No change was made in the other care of the sick. The local treatment remained the same (cleansing with solutions of boric acid); the serum was the only new element introduced.

During the years 1890, 1891, 1892 and 1893, when no serum was used, the hospital treated 3,971 children, with a mortality of from 47.64 per cent to 58.8 per cent. an average of 51.71 per cent. From February 1st to July 24th this year, there were 448 admissions and 109 deaths, a mortality of only 24.5 per cent. That this improvement was not due to a mild form of the disease this year is shown by the statistics of the diphtheria ward of the Trousseau Hospital, which admitted during the months of February, March, April, May and June this year 520 children. None of these patients received serum treatment, and the mortality was 60 per cent.

Operative cases have previously given an average mortality of 73.19 per cent. From February to July this year the mortality was only 49 per cent. under serum therapy. During the same period at the Trousseau Hospital, without the use of serum, the mortality of operated cases was 86 per cent. Of the 448 cases treated, 128 were found on bacteriological examination not to have diphtheria, and 20 died immediately on entrance, without receiving serum treatment. Of the other 300 cases of true diphtheria, 78 died, a mortality of 26 per cent. In 65 cases guinea-pigs were inoculated with bacilli from the membranes; 60 of them died within 30 hours, and three within a week, two only recovering.

Every child at entrance was given 20 c.c. of the serum in a single injection, under the skin of the flank. If bacteriological examination showed that the patient did not have diphtheria, the injection was not repeated. The injections made into the subcutaneous tissues were not painful, and in a few moments the serum was absorbed. In the great majority of cases there was no local reaction, and only where strict antiseptic precautions were neglected. In only three cases did an abscess occur, which healed rapidly after incision. In cases of true diphtheria, 24 hours after the first injection a second was given of from 10 to 20 c.c., which was usually sufficient to bring the case to a cure. The pulse and temperature were taken as a guide. If these remained elevated a third injection was given. The average weight of the children treated was 14 kilos, so that at the first injection they received a little more than a thousandth of their weight in serum. The minimum quantity of serum employed in any case was 20 c.c., the maximum 125 c.c. During the convalescence, some days after the injection of serum, an eruption resembling urticaria was occasionally noticed.

The general condition of the children treated by serum rapidly improved, provided the disease was not too far advanced. The appearance of most of the children was entirely altered from previous years. They are not pale and livid, but their color is bright and they appear gay and interested. The appetite quickly returns, and there is but slight loss of flesh. Their stay in the hospital is notably shortened.

The effect of the serum on the local lesion is most marked; within 24 hours the false membranes cease to extend, and within 48 hours they become detached, always by the third day; in seven cases only did they last longer. Bacilli disappeared from the throat at the same time with the false membranes, cultures ceasing to give colonies of the Klebs-Löffler bacillus by the third or fifth day.

The temperature rapidly falls under the action of the serum; in the less severe cases the decline often occurs the day after the first injection, and is scarcely noticeable after the second day. The fall is often so sudden as to be represented by a vertical line upon the temperature chart, as if the disease had been arrested at one blow. In the severe cases the defervescence does not begin until after the second or third dose, but then falls by a rapid lysis.

The pulse varied from 120 in the benign

to 140 in the severe cases, and was more slowly affected by the serum than was the temperature, frequently remaining high after the fever had ceased, and never reaching a normal rate before the temperature. After treatment by serum the pulse was never observed to have the irregularity during convalescence which was so frequent in former times.

Persistent and abundant albumen in the urine was noted only in certain of the most severe cases, and there is little doubt that the serum prevents the action of the toxin upon the kidneys and lessens to a large extent the number of cases.

The accidents consecutive to diphtheria are much rarer among those treated by serum. There were a few cases of paralysis of the palate of short duration, one case of paralysis of an inferior limb, and one of general paralysis in a child nine years old, who entered on the sixth day of the disease. The paralysis appeared three weeks after recovery, and the child died of asphyxia while eating a biscuit. Three children died of syncope—two within 26 hours of entrance, and one, who had had measles, on the third day.

From these experiences there seems little doubt that every case of pure anginal diphtheria will recover if treated in season with immunized serum.

The results in mixed cases were similar to those in animals. Cases of diphtheria associated with the staphylococcus pyogenes are more severe, but all the five cases observed recovered after a longer period. The amount of serum used varied from 30 to 50 c. c. The association with the streptococcus gave rise to the gravest cases, of which there were 35 with 12 deaths (34.2 per cent.) Omitting four who died within 24 hours of entrance there was a mortality of but 25.8 per cent. The duration of these cases was the longest, the children who recovered being at least 15 days in the hospital. Under the use of serum the general symptoms were notably less severe, the pallor of the face less, the false membranes became detached more easily, and the swollen glands ceased to increase after a sufficient injection. In these cases the serum did not bring the rapid fall of temperature noticed in true diphtheria. In case the disease is to terminate favorably, the pulse falls within the first two days to 120, and remains at that rate for a considerable time.

The statistics of the operated cases, the details of which we cannot give here, point strongly to the conclusion that in cases of laryngeal obstruction operation should be delayed as long as possible after giving the serum. During the period of serum treatment only 40 per cent. of the cases came to operation, as compared with 50 per cent. or over in previous years; but of these 121 cases, 102 were operated before the injection of serum, or within 12 hours of the first dose; 14 between the 12th and 36th hour after the beginning of treatment; and but five more than 36 hours after receiving the antitoxin. It is impossible to say how many of these would have escaped tracheotomy if the serum had been administered sooner, but there is no doubt that with the serum treatment, tracheotomy should in a large majority of cases be replaced by intubation. If the imminent danger of suffocation can be thus relieved for one or two days, there is little doubt that sufficient time will be gained to obtain a cure by means of the serum.

The local treatment in connection with the serum therapy should be of the simplest nature. No swabbings or paintings with caustics or carbolic acid or corrosive sublimate. A douche or boric acid solution to the liter or boiled water, two or three times a day, is quite sufficient.

In concluding, Mr. Roux said that they were convinced that with better means of isolation than existed at the Paris hospital the mortality could be still further reduced.—*Boston Med. and Surg. Journal.*

For Blepharitis

Millendorf recommends, (*Col. and Clin. Rec.*)

℞ Red oxide of mercury..... gr x
Vaseline..... f ʒ ss

MEDICINE.

Where Our Drugs Come From.

"Principal Exports to the United States" is the title of a pamphlet lately issued by the State Department, which is of especial interest from the fact that it gives the value of our imports and the names of the products and the countries from which they are derived. The report is compiled from the reports of the various consuls of this country, and the figures bearing upon the extent of the drug and chemical imports are interesting both on account of the magnitude of the commercial interests involved in the trade and the fact that they show that the most remote portions of the earth are called upon to supply our demand for drugs and medicines. The figures given, with a few exceptions, cover the calendar year 1892, and the report is arranged to show the value of goods as "declared for export" in the various consular districts. From the Buda-Pesth and Vienna districts of Austria-Hungary we receive drugs and chemicals amounting to $122,758. From Trieste insect powder and flowers amounting to $71,884. From France our imports include olive oil, drugs, chemicals, argols, dyestuffs, toilet articles and perfumery, and amounted to $2,564,000. Germany furnished us with drugs, chemicals, dyes, colors and essential oils to the amount of $9,193,849. Greece sent us $24,108 worth of sponges. From Italy we received olive oil, brimstone, canary seed, crude glycerine, soap, argols, orris root, almonds, licorice, sumac and essential oils, valued at $4,909,704. The Netherlands sent us cacao butter, drugs and dyestuffs amounting to $366,470. Corkwood worth $1,069,057 and argols worth $131,805 came from Portugal. The Batoum district, Russia, furnished us licorice root valued at $624,363. Spain furnished us cream of tartar, glycerine, licorice, saffron, corkwood, olive oil and canary seed worth $1,505,505. Sweden and Norway sent us $82,055 worth of cod-liver oil and oxalic acid worth $18,090. Little Switzerland sent us anilines, dyestuffs and chemicals worth $139,518, and enough argols and beef extract to make the total $475,760. We received from Turkey in Europe $403,013; attar of roses, $141,929; gum tragacanth, $55,620. From the United Kingdom, which seems to be a sort of clearing-house for the world, we received drugs and chemicals amounting to $12,570,180. British North America sent us $22,003 worth of senega root and $12,664 worth of sulphur. Sarsaparilla worth $67,577; vanilla, $710,580; fustic, $130,913; gum chicle, $475,665; and silver dollars, which are apparently a drug on the market, to the amount of $454,031, came to us from Mexico. China furnished cassia, $164,497; gall nuts, $5,730; and rhubarb, $16,454. Dutch India, gum damar, $64,729; gum copal, $30,452; cassia, $26,593. Japan, sulphur, $226,025; menthol, $23,391; camphor, $522,152. Philippine Islands, indigo, $16,369; ylang ylang oil, $10,002. Turkey in Asia, licorice root, $1,023,710; opium, $451,431. New Zealand, kauri gum, $1,997,607. Tahiti (Society Islands), vanilla, $36,698. Honduras, sarsaparilla, $30,951; chicle, $4,604. Brazil, copaiba, $28,958; guarana, $8,078; castor beans, $22,774. Chili, nitrate of soda, $2,880,643; iodine, $579,313. Peru, coca leaves and elixir, $5,329. British West Indies, sponges, $236,555; dyewoods, $186,842; ginger, $40,734; pimento, 126,400. Dutch West Indies (Curacao), aloes, $3,047. Guadeloupe, vanilla, $1,660. San Domingo, dyewoods, $38,307. Porto Rico, bay rum and oil, $3,494. Canary Islands, cochineal, $17,382; almonds, $3,877. British Africa, argols, $10,088; palm oil, $1,892. Egypt, senna, $36,627. Algiers, corkwood, $22,159. Morocco, canary, cumin and coriander seeds, $4,735. Zanzibar, cloves, $289,688; clove stems, $4,058; gum copal, $51,886. British Asia, Aden, civet, $4,898. Culcutta, drugs, $4,272,076; saltpeter, $518,845. Ceylon, cocoanut oil, $937,331; cinchona, $73,185; essential oils, $73,015. Hong Kong, opium, prepared, $543,091; cassia, $79,170; medicines, $51,418. Singapore, gambier, $733,855; gum copal, $119,493.—*Pharmaceutical Era.*

Thioform as a Substitute for Iodoform.

Dr. Julius Schmidt states that thioform is a grayish-yellow powder, which is a chemical combination of bismuth, sulphur and salicylic acid. It is tasteless and odorless, insoluable, and was first prepared as a substitute for iodoform. This expectation has been verified in so far that surgically its value is equally great, but the specific of iodine, as required in tuberculous affections, is not obtained. When applied to fresh wounds thioform produces a rapid drying of the surface, leading to a more rapid cicatrization than has been observed after the use of any other application. This was noticed even in extensive surface lesions, such as burns, weeping eczema and gangrenous patches, the latter having healed in four days. The author tested the powder in five cases of ulcer of the leg, which had resisted other treatment. The ulcer having been cleaned and disinfected, the thioform was thickly dusted over it, and covered with cotton-wool and a bandage. Every fourth day the whole dressing was changed, and though the patient continued to walk during the treatment, the cure required two or three weeks only. Some pain was occasionally produced, but no sign of irritation could be seen. Similar results in the practice of other surgeons are given. Finally, the author used thioform internally

after having satisfied himself as to its non-poisonous character, and with daily long-continued doses of fifteen grains, better, though similar, results were obtained than with salicylate of bismuth.—*Medical Record.*

Management of Eczema.

Dr. Malcolm Morris thinks that, as a general rule, the less internal remedies we use the better, but that if a constitutional dyscrasia be recognized it must, of course, receive appropriate treatment. When the skin lesions are acutely inflammatory the use of antimony seems beneficial, and the author gives ten or twelve minims of wine of antimony, repeating the dose in an hour, and, if necessary, in two more. Gradually the interval is increased and the dose lessened until six minims are given three times daily, and this is continued until the inflammation subsides. Arterial tension is an indication for the use of this drug, and depression a positive contra-indication. Deficient strength and nerve force may call for strychnia, arsenic, belladonna, phosphorus, quinine, etc., but the author thinks diet has only an indirect influence, through its effect on digestion, the general health, etc.—*Pacific Med. Jour.*

Cause of Death in Skin Burns.

Kianicine (*International Med. Mag.*) has made some experiments to determine the presence of a ptomaine in the blood of animals affected with burns of large extent. In thirty-five experiments the ptomaines were found both in the blood and in the organs, while the blood of healthy animals, prepared in identically the same manner, did not contain this ptomaine. The method of Stas-Otto was employed in the same manner as is done by Brieger for preparing the peptotoxine. Extraction is accomplished at a temperature of 80° C. (176° F.), with alcohol, evaporation, and the digestion of the remainder with amyl alcohol. Next, evaporation to dryness, dissolving the product in water, and purification by means of the subacetate of lead, by the use of sulphurretted hydrogen; and finally a purification by means of ether. This poison develops only in animals burned or scalded, and is not a product of chemical manipulation. Some special reactions are given for it in the paper.

Lactophenin.

Lactophenin is phenacetin: in the group, acetyl is replaced by the group lactyl. It is white fine crystalline powder, with an agreeable bitter taste, soluble in 330 parts of water. Dosage: 0·6 gramme, three times a day. The maximal dose is 1 gram three times daily. It acts as an analgesic in neuralgia, and in full doses as a hypnotic. It gradually reduces temperature, which remains low for a long time. In typhus fever it calms the excitement, stops delirium, and produces sleep, and in typhoid is credited with cutting short the fever.—*Les Nouveaux Remedes.*

Methyl-Blue and Epithelioma.

Dr. Darier, in a communication to the Academy of Medicine of Paris, reports the success of Dr. Mosetig, of Vienna, with the methyl-blue treatment of cancers, though M. Dentu has not with methyl-blue obtained cures. The author relates a series of cancerous tumors of the face cured rapidly by the daily application of a twenty per cent. solution of the drug. He considers the drug to have a specific action on cancer. A daily touching of the sore with the solution will effect a cure; but the good result will be more quickly produced by cauterising the carcinoma with chromic acid or the galvano-cautery. For deep-seated carcinoma he recommends the solution to be hypodermically injected. Tumors whose surface is broken should be covered by a healthy skin-flap on or about the fifteenth or twentieth day after treatment commenced. Dr. Darier presented to the academy a patient who had had epithelioma of the left eye, and was then quite free of the disease, its site being marked by a cicatrix. This was the ninth case the doctor had thus treated, and with success in all.—*Les Nouveaux Remedes.*

Mechano-Therapy in Chronic Diseases of the Heart.

In the *Practitioner*, Eccles writes an article on this subject. He believes the rationale of the treatment of certain chronic diseases of the heart, by a combination of rest, massage, assisted and resisted exercise, followed by outdoor walking carefully graduated, is based upon,—

1. The rest afforded to the overstrained or enfeebled heart by the adoption of the recumbent position for a time.
2. The aid given to the circulation by the mechanical centripetal pressure exercised on the limbs and trunks by massage.
3. The more rapid oxygenation induced by the acceleration of the circulation, and the diminution of peripheral resistance by the same means.
4. The improvement in general nutrition, the elimination of waste products, and the increased metabolism induced by the passive and active exercises in and out of doors.
5. The careful preparation and selection of suitable food, coupled with the aid to digestion afforded by abdominal massage and exercises acting directly on the walls of the abdomen, and exercising pressure on its contents.
6. The substitution of regular, graduated, assisted, and resisted movements for the spasmodic and ill-regulated exercise taken by patients suffering from cardiac functional disturbance, with or without organic lesion.

GYNECOLOGY.

New and Speedy Method of Dilating a Rigid Os in Parturition.

At a meeting of the Obstetrical Society of London Dr. Farrar (Gainsborough) gave the details of two cases in which he had used a ten per cent. solution of cocaine as an application to the rigid os. In one case he had applied the cocaine after endeavoring vainly to relax the cervix by means of chloral, bromide of potassium and morphia and the most persistent attempts at digital and mechanical dilatation, with and without chloroform. He decided upon incising the os and used the cocaine to this end. After five minutes he introduced the finger as a guide to the scissors; and to his surprise found the os widely dilated. In the second case, a primipara, forty-eight years of age, he used every effort as before to produce relaxation, and waited three days before making the application of cocaine, which was immediately successful. In four minutes the os had yielded. He considered the dilatation to be due to the cocaine in both cases.

Dr. Armand Routh said that Dr. Dibbs, of Shankin, had recommended cocaine as relieving the pains of the first stage of labor, and that Mr. Head Moore advised cocaine and boric acid pessaries in cases of rigid os. He himself had found it useful.

The president, Dr. G. E. Herman, said that two cases were rather a slender foundation upon which to base a conclusion, but if Dr. Farrar's results were confirmed by further experience he would have made a valuable addition to our obstetric resources.—*The Lancet.*

Sugar in the Treatment of Uterine Inertia During Labor.

It remained for Mr. Bossi, of Genes (*Rev. Illust. Polytechnique Medicale*), to make practical application of a theory propounded by Drs. Paoletti and Mosso, that sugar taken internally might be found to exhibit as stimulating an effect upon the group of uterine muscles as it has on voluntary muscles. Bossi administered a dose corresponding to an ounce of sugar in about eight ounces of water. A most excellent effect was observed after the first dose in all but one of the cases, the ecbolic action showing itself in from twenty to forty minutes and nearly always lasting till the birth of the child. In the other case a second dose had to be given. The contractions were always quite regular and free from any tetanic tendency.

OBSTETRICS.

The Psychoses of the Climacteric Period.

Prof. P. J. Kowalewski, of Clarkow, in a recently published paper, "Menstruationszustand und die Menstruations Psychosen," says that during the climacterium insanity may appear in two forms: in the one, the course of the disease is periodical, and the attacks accompany the menstrual periods, or occur at the time when these periods are expected but do not appear; in the other, the psychosis has no direct connection with the menstruation, but seems intimately related to all the symptoms of the climacteric. The mental symptoms of these psychoses vary greatly. They may be characteristic of anxietas, melancholia, mania, amentia, or parnonia, etc. Although these symptoms are not especially characteristic, the influence of the climacteric may be easily recognized. Thus, the anxietas precordialis occurs in more or less regular attacks, corresponding to the time of the expected menstruation. The same may be said of the periodical exacerbations of hysterical and epileptic attacks. It is often found that at such times sudden changes in mood and character may develop without such symptoms being characteristic of either melancholia or mania. The melancholia of the climacteric period is especially met with in married women leading an unhappy domestic life, and is often accompanied by attemps at suicide. Sometimes the melancholia is of a hypochondriacal type; at other times it is associated with delusions of a religious character, persecutory ideas, or erotic hallucinations. Mania is a rather uncommon form of insanity during the climacteric, and is generally characterized by hallucinations, sexual excitement, violence, phantastic ideas and obscene behavior. It is usually met with in widows, old maids of not very high morals, and, generally speaking, in person with unsatisfied sexual cravings, or in such who have committed excesses in venery. Amentia does not often occur during this period in the maniacal form; more often in connection with the menstruation in the form of a periodical psychosis or as an uninterrupted attack, with exacerbation corresponding to the menstrual periods. It is often accompanied by an extreme erotism. Particularly characteristic of the climacteric period is paranoia, occurring mostly in old maids with a psycopathic predisposition. The morbid ideas of such persons are concentrated about men, who make love to them on every occasion. They finally accuse their persecutors of having made criminal assaults upon them. The patients believe that a certain man, who is often unknown to them, or may even be living in some other town, maintains marital relations with them. From being persecuted, the patients finally become persecutors, who torment their victims with letters, or even go so far as to make an open scandal of it. In some cases a perversion of the sexual instinct may show itself by persons of their own sex having an attraction for them. These persecutory ideas as regards the men, in which hypnotism, spiritualism, the telephone, etc., figure extensively, together with the sexual delusions and nymphonomaniacal symptoms, are so often met with in the climacteric period that this form may be considered the climacteric insanity *par excellence.—St. Petersburger medicinische Wochenschrift.*

PHYSIOLOGY.

The Resistance of Living and very Vascular Tissue to Gastric Digestion.

John Hunter, in 1772, pointed out the *Post-Mortem* digestion of the stomach and adjoining organs by the gastric juice. He attributed the resisting power of the living organ to "the living principle." In 1856, Pavy showed that the leg of a frog or the ear of a rabbit, introduced through a gastric fistula into the stomach of a dog, would be then digested. Pavy attributed self-preservative power of the living stamach walls to the presence of alkaline blood and lymph neutralising the acid gastric juice. By stopping the circulation at certain points he produced autodigestion of small areas. Claude Bernard thought the protection was due to the mucous coating, but Schiff observed a wound of the mucosa for six weeks, without softening or autodigestion of the deeper coats.

Gaglio injected gastric juice into the bladder of living rabbits, after ligation of the ureters, and no digestion occurred.

Gaspardi and Viola have detached the spleen from its usual position, and maintaining its vascular integrity, introduced it into the stomach through an artificial opening, and it has remained there as long as sixty-four hours undigested. But, as peritonitis had supervened, digestion may have been inactive.

Ch. Contelean (*Archiv. de Physiol., Norm. te Patholog.*), to test this further, has introduced loops of the animal's bowel into the gastric fistula. The animals have recovered, and lived more than five weeks. One dog, operated upon on the 27th of March, was killed on the 4th of May. Several small perforations of the loop of bowel were found, but the wounds had heated by the formation of a continuous epithelial coat between the mucosa of the stomach and intestine; and only at one small area was the intestinal muscle laid bare.

M. Contejean concludes that the stomach is preserved from autodigestion by the epithelium of the mucosa, and by the circulation maintaining the vitality of this epithelium. The epithelium acts, perhaps, by exercising a selective *role* in absorption, hindering, whilst living, the active principles of the gastric juice from penetrating into the depths of the walls of the stomach (experiment of Sehrwald.) When the epithelium is absent, the circulation of the blood sweeping away the digestive juice as the mucosa absorbs it, permits lesions of the walls to cicatrise, and clothe itself anew with a covering of indispensable epithelium. The importance of these observations in connection with operations upon the stomach and the treatment of gastric ulceration is evident.—*Glascow Med. jour.*

The Excitability of Rigid Muscles.

J. Tissot (*Archiv. de Physiol., Norm. et Patholog.*,) as a result of experiments, concludes that (1) cadaveric rigidity is a phenomenon not incompatible with the life of muscles, and its appearance is not a proof of death, that it can appear in living muscles which may remain excitable (electrically, mechanically, or chemically) for a long time afterwards; that (2) the vapour of chloroform acts as an excitant, and not as a coagulant of muscle; and that (3) the sensibility of muscles to certain chemical reagents persists after the appearance of rigidity and disappears last (except in the fœtus, where it has seemed to disappear sooner that mechanical excitability.) The fact that contractility might be demonstrated in muscle washed out with arterial blood even several hours after the appearance of rigor mortis has been long known, and affords support to the proposal recently made in America to resuscitate criminals who have been put to death by powerful currents of electricity.

Treatment of Migraine.

In the *Gazetta Medica di Roma*, the following formula is recommended in the treatment of migraine:

Citrate caffeine	gr. xx.
Phenacetine	gr. xxx.
White Sugar	gr. xv.

Sufficient for ten capsules.
One every three to four hours during the period of the attack.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM JANUARY 27, 1895, TO FEBRUARY 16, 1895.

The extension of leave of absence on account of sickness, granted First Lieutenant Henry R. Stiles, Assistant Surgeon, is still further extended two months on surgeon's certificate of disability.

The extension of leave of absence granted Captain Reuben L. Robertson, Assistant Surgeon, is further extended fourteen days.

The leave of absence, on account of sickness, granted First Lieutenant James M. Kennedy, Assistant Surgeon, is extended one month, on account of sickness.

Lieutenant Colonel Henry R. Tilton, Deputy Surgeon General is announced as Medical Director, Headquarters Department of Dakota.

First Lieutenant Guy C. M. Godfrey, Assistant Surgeon, will proceed without delay from Fort D. A. Russell, Wyo, to Fort Omaha, Neb., and report for temporary duty.

Colonal Charles C. Cyrne, Assistant Surgeon General is relieved from duty as Medical Director Headquarters Department of the East.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDING JANUARY 31, 1895.

Austin H. W. Surgeon: To proceed to New Bedford, Mass., as Inspector, January 18, 1895.

ORIGINAL ARTICLES.

DYSMENORRHEA.

J. CAMPBELL, M.D., SEAFORTH, ONT.

I report a case of dysmenorrhea with anteflexion of the uterus and stenosis of the os internum, treated by rapid dilatation and applications to the endometrium; afterwards with galvanism, followed by a laparotomy with extirpation of both tubes and ovaries, and resulting in complete cure.

History.—Mrs. I. H., aged twenty-six years, married, came to my office on the 18th of February, 1892. She stated that she had been a sufferer at the menstrual periods ever since they began. She blamed a fall she had received when a little girl. She had been married five years, but so far from an amelioration taking place, she was growing worse as the years went by, so that her suffering had now reached an unbearable point. The pains were equal to labor pains in severity for twenty-four hours before the discharge began, and continued in a moderate degree all through the period, which lasted three or four days.

As a result of her suffering she was becoming morose and melancholy, and fear was entertained that some form of insanity might be the outcome at no late day.

Diagnosis.—Upon examination I found a well-marked case of anteflexion with stenosis of the inner os. Found no tenderness of uterus or ovaries, nor any sign of endometritis. She complained of the usual backache and headache of such cases during menstrual periods. The diagnosis was obstructive dysmenorrhea produced, as we thought, by the anteversion combined with the stenosis of the os internum, which was extremely sensitive upon attempting to pass the sound.

Treatment.—I decided to try what medicine and good hygienic measures would do. I prescribed Hayden's Viburnum Prunifolium compound and recommended fresh air and good diet, with moderate exercise.

The husband being somewhat impatient and desirous of early results, and I having mentioned incidentally that electricity would probably be beneficial in her case, he was anxious to have it tried.

Not having a galvanic battery at that time, I took my patient to the office of my friend, Dr. Turnbull, and had the os dilated by means of the negative electrode, the positive pole being placed over either the uterus or the sacrum. This was done three times with no diminution of the patient's suffering. The husband was so anxious that his wife's suffering should be relieved, that I told him that if there was no improvement at the next monthly period, I would get an assistant, go to his house, put his wife under an an-

*Read before the Huron Medical Association, Ontario, Canada.

æsthetic, straighten the uterus and rapidly dilate the os internum. She reported "no benefit"; hence, in company with Dr. Smith, I went to the house on the 20th of March, 1893, with the intention of carrying out my promise. Upon examination, however, Dr. Smith thought that we had better not dilate, but replace the uterus, scarify the os and insert a boro-glyceride plug, which we did. We then taught the patient how to use hot water injections and insert the plug in question herself. We repeated the scarification once a week.

The next monthly period showed no improvement and the husband asked for a consultation with Dr. Gunn, which was agreed to.

The doctor and I met and decided to dilate by the rapid method. We used Palmer's dilator, and afterwards plugged the cavity of the uterus with iodoform gauze, which we left in for three days for the purpose of keeping the os open and for securing drainage.

Once more the patient reported that the pain at the monthly period was as severe as ever.

We resolved to dilate more fully with Goodell's dilator, at the same time incising some of the fibers of the internal os and making an application to the whole endometrium. On the 20th of May we met, and having anæsthetised the patient thoroughly, dilated the os, cutting some of the fibers with a probe-pointed bistoury, and made an application of carbolic acid, full strength, packed with iodoform gauze as before, inserted the usual plug and left her.

Report after next period: "No alleviation of pain." During all this time the patient was on good tonic medicine with the best hygienic surroundings.

In this manner the latter part of May and the whole of June was passed with no permanent improvement. The patient and her husband were losing heart and wished to know what more could be done.

I advised them to take counsel of Dr. Temple, of Toronto, a specialist in diseases of women, which they consented to do. Accordingly in the early part of July they proceeded to Toronto with a letter explaining all we had done in the case.

After thoroughly examining the patient, he advised her to return and allow me to treat her still with galvanism, as he considered that method had not had a fair trial.

Having secured a galvanic battery in the meantime, I was prepared to carry out his advice.

On July 17th I gave the patient her first *séance*, using the smallest of the graduated dilators manufactured by Waite and Bartlett of New York. Dilated again on the 24th; then on the 31st of the same month, and so on about once a week, but avoided coming within about four days of the menses. This treatment continued through the months of August, September, October and November with varying results; sometimes the patient reporting an improvement. and at other times that she was "no better."

I dilated until the second largest size passed the os internum without much trouble, beginning always with a smaller size, but gradually increasing until, at last, the largest size passed. There was no anæsthetic used, and very little pain was experienced except when the dilator passed the internal os, which it generally did with a jump.

I generally began with fifteen milliamperes and gradually raised the strength to thirty or forty, lowering the power when pain was complained of. I used a bivalve speculum and had the patient on her back in the gynecological chair, by which I was enabled to watch the electrolytic action going on.

I always inserted a boro-glyceride plug, and enjoined her to go to bed for twenty-four hours after the operation. Sometimes I administered an opiate at bedtime.

About the middle of November, my patient becoming somewhat restive, I wrote to Dr. Lapthorn Smith, of Montreal, an authority on both galvanism and diseases of women, giving him a full history of the case with treatment pursued. He wrote urging me to persevere in the treatment, but to give two *séances* in the week, and he believed that I would be ultimately successful. My hands being strengthened by this advice, I went on with the *séances*.

During December and January the patient materialized twice a week, except when monthly flow prevented, taking her last *séance* on the 3d of February, 1894—twenty-one in all.

I had by this time arrived at the conclusion that there must be trouble of an obscure nature in the ovaries or tubes, or both, and that any amount of treatment directed to the uterus would fail to cure her. I considered, reasoning on the principle of exclusion, that all means having failed, an operation was now indicated as a last resort, to render "life worth living." I advised a laparotomy and mentioned my friend Dr. Gunn as a careful and successful operator in such cases.

After a delay extending from the 3d of February till the 4th of July, during which time all treatment was suspended, the operation was performed. During the period of inaction the pain increased in severity so as to render her life intolerable.

On the 4th of July last Dr. Gunn performed the operation, being assisted by Dr. Turnbull and myself. Both ovaries and tubes were removed. The ovaries were found slightly enlarged; they contained small cysts, varying in size from a bean to three times that size and numbering from eight to twelve in each ovary. Had she lived a few years in this condition she would in all probability have developed large cystic ovaries, multilocular in character.

The writer attended to the after treatment. The wound healed by first intention. The patient made an uninterrupted recovery. She was troubled with headache for some time, but neither pain nor menstruation returned. With fresh air, exercise and cheerful society she gained strength and soon resumed her wonted cheerfulness. The result of the operation was all that could be desired.

REMARKS.—(1). We think that all known means should be tried—as we did in this case—before a laparotomy, which is in itself a mutilation, be resorted to.

(2). We do not think that cystic disease of the ovaries could have been diagnosed in this case, as there was an entire absence of those symptoms which usually guide us in such cases, and the fact that Professor Temple failed to diagnose the conditions of those organs would lead us to this conclusion.

(3). Where the cause is uterine—as it more frequently is—the galvanic treatment is invaluable and should in all cases be tried before a laparotomy be resorted to.

(4). We think that in cases like this where pain begins before the flow, showing that it is ovarian or tubal in origin, an operation is more frequently necessary than when it originates from other causes; of course when other means fail the indication is clear.

(5). In conclusion we would say that the operation is a tolerably safe and successful one, the principal objection being that it unsexes a woman. However, we would say that when all reasonable means fail, by all means let laparotomy be performed with proper precautions and with as little delay as possible.

AUTO-INTOXICATION.

J. R. LEMON, M.D., ST. LOUIS, MO.

The tendency in medicine to-day is to study the origin of disease. We are not satisfied, neither should we be, to classify symptoms, give them, collectively, a name and consider our work done.

A physician that works in this manner should retire from the profession at once, as he is not capable of appreciating the responsibilities of his work.

As Bouchard says, the causes of diseases may be many, but the processes following those which produce disease can be relegated to four types. These four chief pathogenic processes are: *first*, primary elementary dystrophies; *second*, nerve reactions; *third*, disturbances antecedent to nutrition; *fourth*, infection. In attempting to place before you in a concise manner these thoughts upon auto-intoxication I will have occasion to refer to the process of disturbances antecedent to nutrition, because this, in my opinion, is the most important factor in the development of chronic diseases, and one that should not

be overlooked when attempting to prevent the development of the acute.

To understand the antecedent disturbances we must first be acquainted with the process which takes place in all healthy tissue, and which we term metabolism. For the purpose of illustration we may take the instance of a muscle of definite structure; it enjoys a free supply of blood and displays, during contraction, energy, heat and sound. It produces certain chemical substances, carbonic acid, water, etc. The blood becomes venous, *i.e.*, loses oxygen and certain elements that supply nutrition to the tissue. The character of the changes that take place in the muscle will depend largely upon the material supplied to the tissues of that muscle. Thus the protoplasm acts on and alters the lymph, and the lymph acts on and alters the protoplasm, this constituting the vital process, the life of tissues, so that it is apparent that the healthy activity of the tissue will depend upon the kind of material supplied. In considering the metabolic changes in the tissues, we must always remember that if the waste material be carried from the tissues by the blood, these products of cell activity must be eliminated by the emunctories, that the blood may be relieved of its load of waste in order that it may carry again to the tissues the material prepared for their nutrition and the oxygen that must be incorporated in order to have healthy cell activity.

Now we can see how much we must depend upon the emunctories to relieve the system of the poison produced in the metabolism of tissues, and in order that their functions are properly performed, it is necessary that the blood, circulatory apparatus and nervous system be in good condition. So here we are again liable to have a double reaction, the emunctories failing to act properly if either the blood, nervous system or circulatory apparatus become disordered, or the emunctories fail to functionate properly. That the primary cause of disturbances in metabolism may be looked for from two sources, *i.e.*, the product supplied by the blood for pabulum and the oxygen, admits of no dispute. If the plasma takes to the tissues a supply that is over-rich in various constituents, that contains poisons that have not been eliminated by the emunctories, or that is deficient in nutritive principles, or if the supply of oxygen is insufficient from any cause, the tissues will not be capable of performing their metabolic changes in a proper manner. We will look for cause of interference with metabolism which originate in the intestinal tract. For instance, we have a patient, as all have had, who presents himself for treatment and complains of feeling much depressed in the morning upon awakening, slight headache, probably has slept poorly, is dizzy upon attempting to rise from bed, possibly almost falls while washing his face, is very sensitive to slight changes in the temperature—in other words, takes cold easily, disturbances of vision, and possibly contraction of hands, as pointed out by Kussmaul, Beaumetz and others. In this case we examine the stomach carefully and find that there is dilatation; there is also eructation produced that may become fetid, still, owing to the inactivity of the muscular coat of the stomach, eructations are not always present. Regurgitation with acid odors may take place. This is positive evidence that there is fermentation in the stomach. The feces are generally acid and peculiarly offensive; and upon careful inquiry we may find that although the operations are soluble there is a feeling that the act is incompletely performed, and there is likely to be burning about the anus. In such a case we will find congestion of the liver, because the organ has attempted to prevent the poisons generated in the intestinal canal from getting into the general circulation. The metabolism in the liver becomes weakened, and eventually the organ becomes indolent and allows the poison to enter the general circulation and we have, as a result, auto-intoxication.

Again, we have the nervous system exposed to a shock; there is a disturbance in the circulation; the cutaneous vessels are contracted, and there is an increased amount of blood in the central organs; the great regulating apparatus, the kidney, does not respond; the equilibrium is not re-established and, as a result, we have possibly a catarrhal condition of the common bile duct which interferes with the outflow of bile. There is also suppression of the part taken by the liver in dis-assimilation, and waste products that should be eliminated are reabsorbed and the result is auto-intoxication which

would be of much more frequent occurrence if it were not for the permeability of the kidneys. In this we have a constant menace to the entire economy, for the irritating products which escape by the kidney are likely to irritate that organ to such an extent that it may fail to eliminate the poisons that have been absorbed from the liver. Therefore it is the duty of every physician to watch and investigate these important emunctories, and every care should be taken to relieve them of the injurious effects of the elimination of these poisons by diluting them as much as possible.

In diseases of the air passages auto-intoxication is so palpable to everyone that we need hardly dwell upon the subject. The accumulation of carbonic acid and other waste products in the system, which should be eliminated by the lungs, is one reason why these diseases are often so difficult to manage and why pneumonia, for instance, is such a fatal disease, the gravity of disease increasing in proportion to the amount of eliminating lung tissue involved; in other words, the death of the patient from pneumonia is caused by auto-intoxication.

In concluding, I repeat, that in those cases of serious impairment of the metabolic changes in the tissues; where oxidation is incomplete; where the nervous system is unstable; the circulatory apparatus is defective; the kidneys, lungs, skin, bowels or the liver are being overworked, either from the products of dis-assimilation or mal-assimilation, and in spite of those cases where one or more of the emunctories are defective in themselves, consider the possibility and the probability of auto-intoxication.

Remember again, that from these causes the primary disturbances antedating the nutrition of every form of tissue in the body originates, that in these disturbances we often find the commencement of not only such diseases as Bright's disease of the kidney, diabetis, acute yellow atrophy of the liver, but that carcinoma, sarcoma, etc., may have their origin from the same cause. And, last but not least, it is the duty of the physician of to-day to guard against the accumulation in the system of such products as poison the tissue, such as cause auto-intoxication, and in this way disturb the general nutrition.

TUMORS OF THE TONSILS.

O. M. WATERMAN, M.D., Milwaukee, Wis.

While the soft palate appears to be a favorite seat for neoplasms, tumors of the tonsils are by no means rare, and benign tumors are fortunately far more frequent than cancerous growths.

Speaking of the former, we find almost every variety represented, cysts, fibromata, lipomata, papillomata and angiomata; more rarely myxomata and adenomata. The tumors of papillomatous structure are very frequent and, if not large, hardly give rise to any distressing symptoms; when more extensive, they hinder the process of swallowing and occasionally produce dysphagia. They differ in size from that of a pea, to diffuse masses involving the velum palati and the pillars; in the latter case they are very apt to recur after removal. Lipomata and angiomata are rare, while fibromata are more frequently found and their growth is slow and painless.

An interesting case is reported by Lefferts in the "Transactions of the American Laryngological Association," 1889. The patient, a man fifty-five years old, had a fibroma extending from the right tonsil almost to the opposite side of the fauces; the tumor was pedunculated but not vascular. After breathing became seriously interfered with, the tumor was removed with the wire ecraseur and without hemorrhage. In another case, reported by Fitzgerald in the *Australian Medical Gazette*, a fibroma, two and a quarter inches long and one and a half inches thick, was removed with a cold snare without difficulty. Fibro-enchondroma and cystoma, are of rare occurrence. The former is removed by enuclea-

tion, the latter by incision and the injection of an irritating fluid exciting inflammation. Lymphadenoma has been found in leucemic subjects, and a case is reported by Lennox Browne (*Journal of Laryngology*, July, 1891,) where the left tonsil was converted into a large red tumor, smooth, not painful and non-fluctuating. The right tonsil appeared hypertrophic. Cervical and axillary glands were enlarged, but the spleen was normal. Masses weighing about an ounce were removed with the cold snare. The microscopical examination showed the characteristics of lymphoid cells.

That errors in making a diagnosis are possible, is illustrated in Frank's case. A male, forty-six years of age, had much enlarged tonsils and adenoid vegetations in the nasal pharynx. The case seemed to be one requiring tonsillotomy and removal of the adenoids, which was done. Relief was only temporary, and microscopical examination of the recurring growth revealed a sarcoma, which terminated fatally in a comparatively short time. Morell McKenzie advocates interstitial injections of acetic acid solution in such cases. The prognosis in all tumors such as we have mentioned is favorable, and removal can be accomplished, mostly without difficulty. In tumors with a pedicle it might be done with a snare, scissors or galvano cautery, but a flat growth has to be removed with a sharp spoon and afterwards cauterized. Angiomata must be treated by electrolysis.

We now come to the malignant neoplasms of the tonsils. We have stated that fortunately these are comparatively rare. McKenzie found in 8,289 cases of tumors of the tonsils, only three malignant growths. Whether malignant tumors are of primary or of secondary origin is yet an open question. Two forms are most frequently found—sarcoma and epithelioma; the former seems to prevail more among females and presents to the eye a round, smooth tumor, which ulcerates sooner or later to a greater or smaller extent. Epithelioma is more painful than sarcoma, as disintegration takes place at a very early date. A characteristic of malignant tumors of the tonsils is the lancinating pain in the ear. Other symptoms are swelling of the lymphatic glands, fetorous, emaciation and hemorrhages. While the diagnosis is not difficult for anybody familiar with the rhinoscope, the difference as to the histological structure is not easily ascertained; in fact the microscope gives better evidence in cases of epithelioma than in cases of sarcoma. It also happens that mistakes are made between malignant neoplasms and tubercular or luetic lesions, especially when the characteristic knots and papillary excrescences are absent, and only the therapeutic trial with specific remedies and examination of extirpated parts can be decisive.

The prognosis for sarcoma and epithelioma must of necessity be unfavorable, except in cases which are subject to a spontaneous retrogressive metamorphosis.

If there is no surgical interference, death usually occurs within twelve months, and it seems that in many cases the operative interference forms a stimulus to the activity of the growth. Death is caused immediately by inanition, cachexia, hemorrhage, or edema of the epiglottis or the larynx.

The only operation promising a lasting success is the extirpation of the tumors from the outside; other procedures may give temporary relief, but can only be considered palliative; and in fact the chances for success are not promising, as the operation is difficult on account of the anatomical relations, and secondary pneumonia is to be feared.

The tables show a mortality of forty-five per cent., but as not all fatal cases are reported it will not be amiss to consider the mortality much greater.

As to the radical operation and its procedure, two methods principally are to be recommended. The first is Czerny's operation, which is conducted as follows: After tracheotomy has been performed an incision three inches long is carried from the angulus oris downward to the anterior border of the masseter, and thence to the level of the os hyoideum; the maxilla is then divided to the third molar tooth. It might be necessary to cut through the stylo-hyoideus, or styloglossus muscles, the hypoglossal and glosso-pharyngeal nerve and also to ligate the laryngeal artery and other vessels. The maxilla is reunited by silver wire sutures, and the wire is turned around the neighboring teeth as an additional hold. Drainage being established, the tracheotomy tube is left *in situ* for a number of days. The wire sutures are

left indefinitely. The wire around the teeth must be removed in about two weeks.

The second method proposed is Mickulicz's operation. This has a tendency to prevent the entrance of blood into the air passages, and so inhibit secondary pneumonia and other dangerous occurrences. He makes an incision four or five inches along the anterior border of the sterno-cleido-mastoid, the jaw is then divided and the ramus ascendens dissected, and the mouth and the pharyngeal cavity not being exposed, the entrance of blood into the larynx does not occur. The operation might also be favored on account of avoiding those distorting cicatrizations following operations of the hard palate and the base of the tongue. Pharyngotomy has not given any encouraging results.

At the conclusion of this sketch, I wish to mention that no case of malignant tumor of the tonsils can be pronounced cured if three to four years have not elapsed without recurrence taking place.

COMMUNICATIONS.

ENDOMETRITIS FOLLOWING ABORTION; DILATATION AND CURETTING; VENTRAL HERNIA WITH STRANGULATION OF OMENTUM; FIBROIDS OF UTERUS; CARCINOMA VAGINA; CARCINOMA UTERI.*

E. E. MONTGOMERY, M.D.,† PHILADELPHIA.

Before you is a patient thirty-five years of age, whose father died of apoplexy; her mother and one sister are living and in good health. She has no hereditary tendencies and enjoyed good health as a child. Puberty occurred at sixteen, the flow was regular, lasted three to four days and was profuse. She was married at seventeen and had five children, the last one in May, 1893, which was still born. Her labors were easy and the puerperium normal. She was never confined to bed for more than ten days. She had four miscarriages, the last one in August, 1894. The present trouble began following this miscarriage, since which time she has had persistent metrorrhagia. She has had a continuous discharge of blood until her admission, since which there has been no bleeding. Beyond hemorrhage she complains of no special symptoms.

The subject of uterine hemorrhage is of very great importance and should always receive very careful consideration at your hands. We should permit no patient suffering from uterine hemorrhage to go without careful examination, and if physical examination and inspection of the cervix do not disclose anything as a cause, the cavity of the organ should be thoroughly explored. Hemorrhage may arise from disease of the uterus itself, or from a diseased state outside of it, so that it is well to determine whether there is not an actual local cause for the symptom. The external condition which may produce hemorrhage may be either constitutional or local. Of the former we have disease of the kidney, of the heart, or of the liver, all of which, by their obstructive influence, may increase the congestion of the pelvic viscera and thus produce hemorrhage. In addition to these constitutional conditions we may have hemorrhage as a result of scurvy, or as a preliminary symptom of the exanthematous fevers. Local conditions outside the uterus, which give rise to this symptom, are those which interfere with the circulation in the organ; thus, a growth situated in the pelvis, producing pressure upon the return circulation, increasing

* A clinical lecture delivered at the Jefferson Hospital, Philadelphia.

† Professor of Clinical Gynecology in the Jefferson Medical College; Gynecologist to Jefferson and St. Joseph's Hospitals.

the congestion. Such growths are ovarian, parovarian, broad ligament cysts, ectopic gestation, or the presence of inflammatory exudation. We have carefully examined this patient and find no evidence of any constitutional disease which may produce interference with the circulation, nor is there any indication of disease outside of the uterus, so that we feel assured the latter organ must be the seat of the disorder.

Careful examination in her case reveals that there is an inflammation of the endometrium from the appearance of the cervix, and this of itself should lead us to make a thorough and careful exploration of the uterine cavity. To accomplish this it is necessary to dilate the cavity of the organ. This may be accomplished either by slow or rapid dilatation. The slow method of procedure consists in the introduction of tents, either sponge, tupelo or laminaria, by which the cavity of the organ is dilated through the absorption of the moisture and retention of the tent. It may be also accomplished by repeatedly packing the cavity of the uterus with gauze. This method of procedure was introduced by Vulliet, and he was able not only to accomplish the dilatation to a degree to permit the introduction of the finger, but also the inspection of the entire uterine cavity. These methods of procedure, however, are slow, and it is preferable that it should be accomplished more rapidly. For the rapid dilatation of the uterus we have a number of dilating instruments which act on the principle of stretching the cervix uterine cavity until it can be explored either with the finger or by means of a curette. The majority of instruments act by separating the blades, either parallel or slightly divergent until the cavity is pretty well dilated. The plan I shall show you, and the one which I prefer for the reason that it accomplishes the dilatation by stretching all the fibres of the cervis, is through the introduction of graduated bougies, increasing these up to the desired size for the dilatation. The dilatation in this way can be accomplished with less danger of tearing, with less hemorrhage and with less irritation of the canal. It is important, however, in using these bougies, to exercise the greatest care for fear that in the introduction of the instruents, one after another, until the dilatation has reached the desired size, a rupture of thinned or fatty walls may occur.

After the uterus is dilated, we use a curette, preferably a sharp, fenestrated instrument, with an opening through its handle. This is introduced and withdrawn from the uterine cavity, turning it in every direction so the entire cavity of the uterus will have been curetted. As the debris is scraped off, the fluid passing through the handle washes it out, keeps the cavity clean, and prevents a collection of blood within it. This irrigating fluid may consist of from a one-half to one per cent. creolin solution, or a solution of carbonate of soda, one or two ounces to the gallon of hot water, using the water quite hot, and thoroughly irrigating the cavity to thus remove all the mucus from it, after which pack the uterine cavity with iodoform guaze. It should be carried to the fundus of the organ, filling it up, and serves the purpose of keeping the walls separate, making pressure upon the parts and decreasing the amount of bleeding. It presses upon the raw surfaces until plastic material is thrown out, glueing up their vessels by its presence, and through its capillary action as a drain, facilitates the removal of ptomaines which may form, and decreases the probability of septic infection and septic extension.

I have repeatedly endeavored to impress upon you the importance of care in dilatation and curetting, for fear the wall of the uterus may be punctured, and make an opening into the peritoneal cavity. This is particularly important in those cases in which abortion has frequently occurred. Only recently a number of cases have been recorded, in which the cavity of the uterus has been perforated with placental forceps following an abortion, in the endeavor to remove portions of the placenta, and the first intimation the operator had of the puncture was the presence at the external os of a loop of intestine, drawn down by the forceps. It should be the rule in such cases not to use placental forceps without the introduction of the finger as a guide. In a case in which the uterine wall has been punctured, it would not be safe, of course, to proceed with the irrigation of the cavity for fear the fluid may escape into the abdomen. In such cases the cavity should be at once packed with iodoform gauze to prevent leakage into

the abdomen. In addition to acting as a tampon and affording drainage, the gauze serves as a stimulant to the contraction of the uterus, through its presence as a foreign body, and thus promotes increased involution; it serves as a great advantage in cases of subinvolution, causing the size of the organ to be rapidly decreased. A second piece of gauze is put in the vagina, raising the uterus upward. The gauze may be permitted to remain for three or four days, the vulva being covered with a gauze pad which will be frequently changed. In performing this operation we exercise as thorough antiseptic or aseptic precautions as we would if we were preparing to open the abdomen, for we realize that through the sinuses of the uterus and its abundant vascular and lympathic systems, we may have rapid absorption of material which may be carried to different portions of the body and produce either local or general septic symptoms. The gauze will be removed at the end of four days and the vagina will then be irrigated twice in twenty-four hours, using either 1:30 sulphurous acid solution, or 1:3000 acid sublimate. If the patient should suffer pain we will have her bowels freely evacuated with a saline purgative and the ice bag will be placed over the abdomen. If the pain should be continuous and attended with some elevation of temperature, the gauze packing should be at once removed and, if necessary, the cavity of the uterus may be irrigated with creolin solution or plain hot water, using for this purpose a catheter with a return flow. The plan of treatment indicated is one that is very effective in subinvolution, and in endometritis of hemorrhagic character, and I do not believe that in any case the uterus should be dilated without curetting and packing follows. Indeed, no instrument should be introduced into the cavity of the uterus without we are able subsequently to render it sterile and afford drainage.

Ventral hernia with strangulation of omentum:—The next patient is thirty-three years of age, has had one miscarriage when sixteen, and was in bed nearly a year subsequently. She underwent an operation some three years ago at the hands of a prominent physician in this city. She was in bed nine weeks following the operation. Nine months after the operation she returned with a small protrusion at the lower angle of the incision, which continued to increase in size and caused severe pain. For four days the bowels were regular, have been moved twice in the last twenty-four hours. She has no nausea or vomiting. The operation was done for pus tubes and she had a subsequent one for ventral hernia. She comes to us to-day with a history of a protrusion at the lower portion of the abdomen. You see it is situated at the central line. I asked her to cough and find it is apparently not influenced by it. While there is a protrusion in the median line, there is a more marked one upon the left side. This protrusion is hard, painful and resisting, the skin over it is somewhat reddened and inflamed, and so far as I can see this protrusion is not directly connected with the hernia. This case is one of considerable interest and difficult of diagnosis, whether the condition is hernia of the omentum, whether in addition to the hernia there is an acute inflammatory trouble upon one side. As I press my fingers into the opening I am able to push back the protrusion of the gut, so I can discover nothing that would give rise to this protrusion on the left side. It is hard, dense, firm and extremely painful. There is no sensation of protrusion of gut, unless it has made its exit through the abdominal wall. I am unable to discover any sign that the latter condition has occurred.

The point to determine is whether this mass is a hernia, and if so, a knuckle of intestine or omentum. That it is not a knuckle of intestine, is evident from the fact that there is no sign of strangulation present here if so large a portion of the intestinal tract had made its exit and was thus strangulated. The condition has been in existence since Friday last, and if a knuckle of intestine was thus strangulated, we would have her suffering before this from symptoms of obstruction, and with vomiting of stercoraceous material. We would expect, also, to find the abdomen greatly distended and all the symptoms of marked strangulated hernia. There would be symptoms of an irritated condition of the peritoneum and more or less effusion of the peritoneal cavity; in the absence of special symptoms, the general symptoms of a developing peritonitis. I do not believe this is a hernia, as we can feel the opening and can

apparently separate it from the mass to one side, the latter inference would seem to be justified.

If it is not a hernia, what is the condition? The redness of the surface, the size of the mass, its tenderness, would lead us to believe that we had an acute inflammation, with development of an abscess. It may be interesting to determine why we should expect an abscess in this situation. It is not unusual to find that points of induration in the abdominal walls following an operation, may break down and suppurate. This may have been the explanation in this case. I do not propose, however, to make an opening at once into this, even though it presents all the symptoms of an abscess, as it would be very unjustifiable to risk such a procedure unless we are absolutely certain that we have excluded the possibility of hernia, as every measure should be exhausted that would favor such elimination. So prior to opening this cavity I shall make a puncture with an exploring needle and see if we can obtain pus. Thoroughly cleansing the surface and having a clean instrument, I make this puncture and do not find, as I had expected I might, any indication of pus. There is a free discharge of blood, showing there is some congested tissue within. Having relieved the congestion through this puncture, by manipulation I find I am able to dislodge a small mass from the cavity here, and this mass can be pushed back through the ventral opening, so we have had a hernia, not of a knuckle of intestine, but of a portion of the omentum, which has been so firmly forced into the abdominal walls as to give rise to this painful tumor and to the presence of external redness.

You can now appreciate the importance of having exercised the precautions that are done to avoid the possibility of any error. Had I proceeded upon the theory that this was an abscess and made an opening, I would have injured the omentum, rendered its return a source of danger and might possibly have injured a knuckle of intestine. So in every procedure of this kind, even where you feel there is reasonable certainty for your assurance, leave no means of completing your diagnosis unused, but resort to operative procedure. The puncture with the exploring needle, even though it may have been a knuckle of intestine, would not have had any injurious effect. It would have merely permitted the escape of any retained gas and by decreasing the size of the protruding mass would favor its reduction.

A compress will be placed over this opening to prevent the further escape of bowel or omentum. The patient should either be subjected to radical operation for the cure of the hernia, or directed to wear a pad or truss that will prevent its further escape. In addition to the difficulty of diagnosis in this case, it is of particular interest from the fact that the gentleman who has operated upon her twice, is one who claims to be particularly free from the accidents and sequelæ of abdominal surgery, and lectures in very strong terms his colleagues who are engaged in similar practice, for their failures, citing them as evidences of bad surgery. She underwent two operations; in the first place for removal of pus tubes, and second, for relief of ventral hernia. She still has a hernia in which there has been a portion of the omentum pushed out and pushed into the abdominal wall between the muscle and superficial fascia. This condition is one which may occur in spite of every precaution. Ventral hernia is so undesirable that we endeavor in every way to obviate its occurrence, yet in spite of all measures we take, it does occur. The gentleman who has operated upon this patient twice, is a man of large experience, a man of ability, a careful surgeon, and the mere fact that he has done the operation is an indication that every measure which could have been exercised has been employed to prevent this occurrence.

Fibroids of Uterus.—The next patient is 27 years of age, puberty occurred at 15, with no unpleasant phenomena. She has been married three years, had one miscarriage after two and one-half months gestation and was confined to bed subsequently three months; now complains of pain during menstruation which lasts ten days; has severe pain in the left side, fever, nausea, vomiting, with constipation of the bowels. The points in the history of this patient are, that menstruation lasts ten days, is quite profuse, and taken in association with the color of the individual, leads us to suspect the possibility of some growth about the uterus. Of course it is not impossible

that this hemorrhage may be a result of conditions resulting from retained products of abortion. As I introduce the finger into the vagina I find the cervix directed anteriorly; passing the finger posteriorly it comes in contact with the posterior surface of the uterus, which may be followed out on the right side of the patient. On the left side there is a rounded mass which projects against the posterior wall of the vagina, is closely associated with or attached to the side of the uterus, and has pushed the latter organ toward the right. This mass fills up entirely the left side of the pelvis. It is evidently not of inflammatory character. We are led to this supposition by the fact that this uterus seems to be impacted in the pelvis, that it is not movable. The mass to the left, while rounded, is very resistant and firm, and the fingers can be passed over it; there is no melting away of the mass into the tissue around it as would be the case in an inflammatory condition. In other words, the mass is defined and limited. While it fills up the pelvis it has a definite shape of itself, and is not merely a mass of inflammatory exudation. Of course we could have a mass in the tube and ovary, the result of inflammation, containing pus, but in such a case we would find there would be more or less inflammatory exudate around it, so the tissue would be hard, difficult to define and limit. In this case the mass is round, closely attached to the uterus, fills up the left side of the pelvis, pushing the organ to the right. I am inclined to believe this to be a fibroid. This, however, is still further increased by the fact of the color of the patient. She is a colored woman and in this race there is an increased tendency to development of such growths. This growth, evidently situated in the broad ligament on the left side, has grown down into the pelvis, pushing the uterus upward and over to the opposite side. The pressure of the mass would give rise to interference with the circulation of the pelvis and increase the tendency to hemorrhage. Whether it is inflammatory or a growth, we would be likely to have hemorrhage. In this patient the only plan of treatment of any service would be operative, and we cannot expect that medicinal treatment would be of much service to arrest its growth or allay the symptoms from its presence. The operation would be removal of the uterus. This might be attended with some difficulty for the reason that such growths developing into the broad ligament, sometimes spread it out, and if they develop low down they lift up the ureter and bladder, and greatly increase the danger in their removal; indeed, in some cases so intimately connected does the ureter become that it is difficult to remove the growth without injury to that duct.

Cancer of the Vagina. The next patient is a woman upon whom we operated some time ago on account of an induration which involved the anterior wall of the vagina and the orifice of the urethra. As I separate the vulva you notice upon the right side and in front a raw surface, a mass of induration which extends up the anterior wall of the vagina nearly to the uterus. We attempted an operation with the hope that we might be able to remove the disease and arrest its growth, but found it involved the entire anterior wall of the vagina and the surface of the bladder to such a degree as to preclude the possibility of its removal. The lower part of the urethra broke down entirely at the time, so it left simply the ring at its upper part, through which the finger was introduced, disclosing the extent of the disease. The operation at that time gave great relief, as it facilitated the more ready evacuation of the bladder and relieved her from the distress and pain attending it. If we were so situated as to be able to accomplish it with safety, this patient would be a good one upon whom to try the influence of injections of the poison of erysipelas. This plan of treatment has seemed in some cases, more particularly, however, in those of sarcoma, to arrest the growth and facilitate the relief from the disease. It is not a plan of treatment we could pursue with safety in a general hospital, and as we have but one ward for treatment of such cases in this institution, we cannot try it.

Carcinoma uteri.—The next patient is thirty-eight years of age; married; had nine children, one miscarriage; complains of hemorrhage; almost constant discharge from the uterus; has lost weight; has severe pain in the lower abdomen; bowels are constipated; has pain on urination; poor appetite. As I separate the vulva I find a bloody discharge; as the finger is introduced into the vagina it comes in

contact with the ragged, indurated surface, which is flush with the roof of the vagina. In other words, the vaginal portion of the cervix is destroyed, and an indurated margin around an opening, which is filled with soft, friable, easily broken-down tissue. As I pass my finger further around the vagina, I find a sensation of resistance, more indurated tissue. I am doing this with exceeding care, as I do not wish to make pressure upon this surface, which will produce hemorrhage. If I introduced my finger into the uterus I would probably cause a profuse hemorrhage. I did not tell you that this patient has been suffering from pain, hemorrhage and discharge, in addition to the loss of flesh; the physical signs disclose the fact that she is suffering from an epithelioma of the uterus, unfortunately one which has progressed to such a degree that there is no plan of operative procedure by which we can hope to arrest its growth. The disease has already infiltrated and extended beyond the confines of the uterus, so that we can afford no hope of radical removal of the disease. All we can do will be to make her comfortable for the brief span of life remaining. The case impresses upon us the importance of early and careful examination, and I cannot urge upon you too strongly the importance of permitting no patient to continue under your care who suffers from prolonged or frequent hemorrhage without a careful examination to ascertain its cause. It is far better for you to lose a patient than to attempt to treat her without having the necessary means to ascertain the condition.

CORRESPONDENCE.

CHILD CRYING IN UTERO.

EDITOR MEDICAL AND SURGICAL REPORTER:

SIR: In THE MEDICAL AND SURGICAL REPORTER for January 5, 1895, is an article copied from the San Francisco *Medical Journal*, entitled "A Case of Child Crying in Utero." I desire to report a case analogous to the one there recorded, albeit with a less favorable termination.

On January 29, 1891, I was associated with Dr. S. D. Bell, of Butler, in a case of labor, of which the following notes were taken at the time: Mrs. S., white, aged thirty-six years. Multipara, this being her ninth confinement, all but two of the labors being instrumental ones. A small woman, four feet eleven inches in height; weighing about one hundred pounds; the left leg and hip are smaller than right side, and she walks with a limp. She gives a history of an attack of infantile paralysis at the age of four or five years, to which the deformity is said to be due. Pelvis deformed, the right half being developed properly, the left half undeveloped.

Labor began at 2 P.M., delivery being accomplished at 7 A.M. of the succeeding day. The head early engaged the upper strait, but on account of its large size and the deformity of the canal, it would not descend although labor pains were strong and regular. As the patient had given birth to children without instrumental aid, some little delay in application of the forceps was made after complete obliteration of the cervix and dilatation of the os uteri.

The high application forceps was then resorted to, the patient being anesthetized. Traction was made but the instrument slipped off. Twice was the process repeated with like results; the amniotic liquor mostly escaping. The low application forceps was now substituted when the cry of the unborn babe was heard. Traction was made and, after three to five minutes efforts at delivery, the crying was repeated with greater vigor, being clearly audible to the four or five persons in the room.

We attempted to hasten delivery and preparations to resuscitate the child were made. Delivery was not accomplished until about twenty minutes after the crying was first heard, a large asphyxiated male child being the fruits of our labors.

All efforts at resuscitation proved unavailing.

As in the case reported, the entrance of air into the lungs is to be explained by the drainage of the fluid from the uterus following the numerous applications of forceps. The medico-legal aspect of cases such as the above would seem to prove an exception to the rules commonly accepted.

Very truly,

G. D. THOMAS, M.D.

Chicora, Pa.

LEPROSY?

EDITOR MEDICAL AND SURGICAL REPORTER:

DEAR SIR: I enclose the report of a case which came under my observation while acting in an official capacity. The parties are all natives of Perry County, Ohio:

On Wednesday, December 19, 1894, there appeared before the Board of Pension Examining Surgeons at New Lexington, Perry Co., Ohio, a young woman, Miss Hannah Garey, aged eighteen years, who applied for a pension as the child of George Garey, a soldier of the late war. The case was a remarkable one, and as rare as remarkable. The mother and a brother older than the applicant, both of whom appeared to be in excellent health, accompanied her. The young man was of fine physique, vigorous and of robust habit. The mother, a well preserved, intelligent woman of forty-four years, whose appearance gave no evidence of ill-health, nor any disorder whatever, affirmed that she had been remarkably healthy all her life.

The applicant, however, presented a sorry contrast to the vigorous health of her mother and brother. Her skin was thickened, rough and swollen. The hands, or what remained of those members, were enlarged to more than double their normal size. On the right hand there remained but the thickened stumps of the fingers which had been amputated by an ulcerative process that had been slowly progressing for a period of sixteen years. The left hand presents the same general appearance as the right, save that the fingers of this hand are lost at the *first* joint, while in the right the ulcerative process has extended to the *second* phalangeal articulation. The feet are enlarged and swollen to twice their normal size; the skin thickened and rough, and the toes of the right foot are lost at the first joint. In the middle of the left sole there is a suppurating ulcer about the size of a silver quarter, the discharge from it being very offensive. There is on the outer aspect of the right arm, above the elbow, a glazed, whitish-colored depression, about the size of the ulcer on the sole, which portends ulceration. At the left radio-carpal articulation there is a deep, narrow ulcer extending entirely around the wrist, which is slowly but surely accomplishing amputation of the hand; the discharge from this ulcer is free and very offensive.

There are some scars on the limbs and arms, showing former ulcerative patches which have healed. Her face also presents evidences of ulceration, the nose, lips and tongue being scarred and disfigured from the same cause. The front teeth are lost and the inferior maxillary shows results of former ulceration by a deep depression on the surface of the gums. There is the peculiar anesthetic condition which characterizes the malady. This affects the entire body, but is especially marked on the hands, feet, forearms and legs below the knee. The mother says that she has to be extremely watchful of her when about the stove, as she would burn her hands or feet unknowingly. The girl is moderately intelligent but can neither read nor write.

This affection began at the age of two years, with ulcerative patches on the lower limbs, hands and feet gradually producing the condition described, and this without excessive pain or suffering to the patient, but with untold care and anxiety to the mother. There are eight children in the family, four older and three younger than this girl. In the youngest, a child of six years, the same malady is developing, being manifest at this time by a marked anesthetic condition of the body, the loss of one or two fingers, and an equal number of toes.

The father was a pensioner; a member of the 187th Regiment, O. V. I., which was stationed for a time at Nashville, Tenn. He afterwards did provost duty at Macon, Ga., until the close of the war. He was considered a man of ordinary good health by his acquaintance; his wife, however, said that for some few years previous to his death, which occurred in March, 1893, he was afflicted with eczema, the discharge from which was very offensive, which resisted all treatment.

That the disease is anesthetic leprosy I verily believe, and I am of the opinion that the seeds of the malady affecting these children came from the soil of the Southland during the soldiers' sojourn there. And, perhaps, that persistent eczema (!) was but the precursor of the malady named which was waiting only for conditions favorable to its development.

Very truly,

G. W. CLEMSON, M.D.

Thornville, Ohio.

TRANSLATIONS.

THE TREATMENT OF SPINA BIFIDA.

Sebileau (*Gaz. Med. de Paris*, Oct. 13, 1894), gives the following treatment for spina bifida.

1. SIMPLE CASES.—(*a*) *Morton's Injections.* Of all of the injections that have thus far been employed, that of Morton alone has remained in use. It is a solution of iodine in glycerin. He replaced the tincture of iodine by a solution of iodine in glycerine in order to evade the dangers of the injection of iodine employed by Velpeau (convulsions, paraplegia, meningitis, suppuration). With a fine trocar the upper portion of the tumor is punctured at a healthy portion of the skin; from 4 to 12 grams of the liquid are withdrawn and from 2 to 4 grams of the solution injected. Rarely a single injection suffices; ordinarily it must be repeated. The results obtained by him appear very favorable; of 71 cases treated 35 were cured, 9 remained unaltered and 27 died. Accidents are less frequent by this method than by the older methods. Death may follow, however, the injection immediately; convulsions and hydrocephalus follow in some cases.

(*b*) *Ligation.* The ligature may be employed when the condition of the lower limbs from the point of view of mobility, sensibility and nutrition do not permit even the suspicion of the inclusion of the nerves in the sac. The end in view is the adherence of the two serous surfaces by their approximation or the necrosis of the tumor. Reynard employed the linear ligature. His procedure consisted in placing upon the sides of the tumor two feather quills joined by a thread. Tavignot employed successfully pincers analogous to the enterotome of Dupuytren. Beaumier fastened the ligature in the scar produced by Vienna paste applied circularly to the base of the tumor. Dubois employed two small metallic plates pierced by a thread and held in place by pins traversing the base of the tumor.

2. COMPLICATED CASES. — *Excision.* This is the true surgical method. Some surgeons practice it with the aid of the galvanic needle or the thermo-cautery with or without previous compression. The use of the bistoury is better. Excision after exploration of the sac, comprises several steps; incision of the skin, dissection of the tumor, the opening and examining of the sac, and the treatment of the vertebral fissure. (*a*) *Incision of the Skin.* If the skin is healthy, mobile, the choice lies between a vertical and a transverse incision; the latter has been practiced by Championière, Périer, etc. It is preferable if the operation be in the lumbar or sacral regions, as is usual, because it is more distant from the genitalia and the anus, and, consequently, less exposed to soiling by the urine and feces. If the skin be red, thin, and excoriated in places, it is

*Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M.D.

necessary to make the incision in a healthy spot.

(*b*) The *dissection of the tumor* will be most easy when the sac is extended and thickened.

(*c*) *Incision of the sac.* It is well to incise the sac upon the sides to avoid injury of the spinal cord; the incision should also follow a parallel direction to the intra-saccular nerves to avoid their section. When the sac is opened it is explored, to see whether or not it contains nerves. If not it may be ligated and resected, if it does it is difficult to decide what to do. Some surgeons advise resecting only the segments of the sac comprised between the nerve cords, leaving the latter in place covered with meningeal flaps to which they are adherent; others advise dividing all, nerves and meninges. It may happen in some cases that no disturbance of sensation or motion will follow such a course.

(*d*) *Treatment of the vertebral fissure.* When closure of the sac is well assured it is necessary to close the vertebral fissure. Here two questions present themselves. Is the fissure narrow, or is it large? If of small dimensions the layers of tissues may be sutured one by one without interfering with the bone; the flow of cerebro-spinal fluid may thus be controlled. If the fissure be large it does not suffice to close the soft parts merely; it is necessary to establish a bony barrier. Two methods are suggested: the one consists in approximating the two extremities of the vertebral blades, this is the method of Dollinger of Budapesth; the other consists in implanting in the cleft some periosteum or bone. If periosteum be implanted it constitutes the method of Robert Hayes; if bone, it is the method of Berger. Dollinger devised his method in 1885. Operating upon a little girl, he broke the two rudimentary vertebral arches of the deficient vertebra, drew them together with a strong forceps and secured them in the median line. Hayes, in 1883, engrafted into the fissure flaps of periosteum taken from the rabbit, with good results. In 1892, Berger reported a radical cure of lumbar spina bifida by means of implantation of a bony plaque from the shoulder blade of a young rabbit. Hydrocephalus may follow a radical cure for spina bifida at an early age.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

INTUSSUSCEPTION IN A CHILD TREATED BY INSUFFLATION OF AIR UNDER AN ANESTHETIC.

Dr. H. Swift (*Australasian Medical Gazette*, No. 8, 1894) reports the case of a child of nine months who had always been healthy, but who suddenly began to scream violently, draw its legs up and kick them out as if in great pain. Vomiting occurred several times. No tumor could be detected in the abdomen. Temperature normal; pulse increased. That evening the child was worse, collapsed, retching violently, screaming, and had passed some blood and mucus by the bowel. Intussusception was diagnosticated, chloroform administered and air insufflated into the lower bowel, and a tumor which had been detected, after the child had been anesthetized, above and a little to right of the umbilicus, and which was about three inches long and two broad, with its axis lying transversely, was kneaded while the insufflation was continued. A gurgling sound was heard and the enlargement was found to have disappeared. Tincture of opium was administered and the child soon recovered its usual good health.

A LOCAL APPLICATION IN LARYNGEAL PHTHISIS.

In *L'Union Medicale Du Canada*, No. 10, 1894, in the treatment of laryngeal phthisis, the following is recommended:

Iodoform	grs. lx
Powdered boric acid	grs. vij
Powdered phosphate lime	ʒ ij. grs. xl

Insufflate into the throat morning and evening.

FOREIGN BODIES IN THE TRACHEA AND STOMACH.

Dr. Glasgow (*Memorabilien Hft.* 7, 1894) was called to a boy of eight years,

*In charge of the translator, F. H. Pritchard, M.D.

the congestion. Such growths are ovarian, parovarian, broad ligament cysts, ectopic gestation, or the presence of inflammatory exudation. We have carefully examined this patient and find no evidence of any constitutional disease which may produce interference with the circulation, nor is there any indication of disease outside of the uterus, so that we feel assured the latter organ must be the seat of the disorder.

Careful examination in her case reveals that there is an inflammation of the endometrium from the appearance of the cervix, and this of itself should lead us to make a thorough and careful exploration of the uterine cavity. To accomplish this it is necessary to dilate the cavity of the organ. This may be accomplished either by slow or rapid dilatation. The slow method of procedure consists in the introduction of tents, either sponge, tupelo or laminaria, by which the cavity of the organ is dilated through the absorption of the moisture and retention of the tent. It may be also accomplished by repeatedly packing the cavity of the uterus with gauze. This method of procedure was introduced by Vulliet, and he was able not only to accomplish the dilatation to a degree to permit the introduction of the finger, but also the inspection of the entire uterine cavity. These methods of procedure, however, are slow, and it is preferable that it should be accomplished more rapidly. For the rapid dilatation of the uterus we have a number of dilating instruments which act on the principle of stretching the cervix uterine cavity until it can be explored either with the finger or by means of a curette. The majority of instruments act by separating the blades, either parallel or slightly divergent until the cavity is pretty well dilated. The plan I shall show you, and the one which I prefer for the reason that it accomplishes the dilatation by stretching all the fibres of the cervis, is through the introduction of graduated bougies, increasing these up to the desired size for the dilatation. The dilatation in this way can be accomplished with less danger of tearing, with less hemorrhage and with less irritation of the canal. It is important, however, in using these bougies, to exercise the greatest care for fear that in the introduction of the instruments, one after another, until the dilatation has reached the desired size, a rupture of thinned or fatty walls may occur.

After the uterus is dilated, we use a curette, preferably a sharp, fenestrated instrument, with an opening through its handle. This is introduced and withdrawn from the uterine cavity, turning it in every direction so the entire cavity of the uterus will have been curetted. As the debris is scraped off, the fluid passing through the handle washes it out, keeps the cavity clean, and prevents a collection of blood within it. This irrigating fluid may consist of from a one-half to one per cent. creolin solution, or a solution of carbonate of soda, one or two ounces to the gallon of hot water, using the water quite hot, and thoroughly irrigating the cavity to thus remove all the mucus from it, after which pack the uterine cavity with iodoform guaze. It should be carried to the fundus of the organ, filling it up, and serves the purpose of keeping the walls separate, making pressure upon the parts and decreasing the amount of bleeding. It presses upon the raw surfaces until plastic material is thrown out, glueing up their vessels by its presence, and through its capillary action as a drain, facilitates the removal of ptomaines which may form, and decreases the probability of septic infection and septic extension.

I have repeatedly endeavored to impress upon you the importance of care in dilatation and curetting, for fear the wall of the uterus may be punctured, and make an opening into the peritoneal cavity. This is particularly important in those cases in which abortion has frequently occurred. Only recently a number of cases have been recorded, in which the cavity of the uterus has been perforated with placental forceps following an abortion, in the endeavor to remove portions of the placenta, and the first intimation the operator had of the puncture was the presence at the external os of a loop of intestine, drawn down by the forceps. It should be the rule in such cases not to use placental forceps without the introduction of the finger as a guide. In a case in which the uterine wall has been punctured, it would not be safe, of course, to proceed with the irrigation of the cavity for fear the fluid may escape into the abdomen. In such cases the cavity should be at once packed with iodoform gauze to prevent leakage into

the abdomen. In addition to acting as a tampon and affording drainage, the gauze serves as a stimulant to the contraction of the uterus, through its presence as a foreign body, and thus promotes increased involution; it serves as a great advantage in cases of subinvolution, causing the size of the organ to be rapidly decreased. A second piece of gauze is put in the vagina, raising the uterus upward. The gauze may be permitted to remain for three or four days, the vulva being covered with a gauze pad which will be frequently changed. In performing this operation we exercise as thorough antiseptic or aseptic precautions as we would if we were preparing to open the abdomen, for we realize that through the sinuses of the uterus and its abundant vascular and lympathic systems, we may have rapid absorption of material which may be carried to different portions of the body and produce either local or general septic symptoms. The gauze will be removed at the end of four days and the vagina will then be irrigated twice in twenty-four hours, using either 1:30 sulphurous acid solution, or 1:3000 acid sublimate. If the patient should suffer pain we will have her bowels freely evacuated with a saline purgative and the ice bag will be placed over the abdomen. If the pain should be continuous and attended with some elevation of temperature, the gauze packing should be at once removed and, if necessary, the cavity of the uterus may be irrigated with creolin solution or plain hot water, using for this purpose a catheter with a return flow. The plan of treatment indicated is one that is very effective in subinvolution, and in endometritis of hemorrhagic character, and I do not believe that in any case the uterus should be dilated without curetting and packing follows. Indeed, no instrument should be introduced into the cavity of the uterus without we are able subsequently to render it sterile and afford drainage.

Ventral hernia with strangulation of omentum:—The next patient is thirty-three years of age, has had one miscarriage when sixteen, and was in bed nearly a year subsequently. She underwent an operation some three years ago at the hands of a prominent physician in this city. She was in bed nine weeks following the operation. Nine months after the operation she returned with a small protrusion at the lower angle of the incision, which continued to increase in size and caused severe pain. For four days the bowels were regular, have been moved twice in the last twenty-four hours. She has no nausea or vomiting. The operation was done for pus tubes and she had a subsequent one for ventral hernia. She comes to us to-day with a history of a protrusion at the lower portion of the abdomen. You see it is situated at the central line. I asked her to cough and find it is apparently not influenced by it. While there is a protrusion in the median line, there is a more marked one upon the left side. This protrusion is hard, painful and resisting, the skin over it is somewhat reddened and inflamed, and so far as I can see this protrusion is not directly connected with the hernia. This case is one of considerable interest and difficult of diagnosis, whether the condition is hernia of the omentum, whether in addition to the hernia there is an acute inflammatory trouble upon one side. As I press my fingers into the opening I am able to push back the protrusion of the gut, so I can discover nothing that would give rise to this protrusion on the left side. It is hard, dense, firm and extremely painful. There is no sensation of protrusion of gut, unless it has made its exit through the abdominal wall. I am unable to discover any sign that the latter condition has occurred.

The point to determine is whether this mass is a hernia, and if so, a knuckle of intestine or omentum. That it is not a knuckle of intestine, is evident from the fact that there is no sign of strangulation present here if so large a portion of the intestinal tract had made its exit and was thus strangulated. The condition has been in existence since Friday last, and if a knuckle of intestine was thus strangulated, we would have her suffering before this from symptoms of obstruction, and with vomiting of stercoraceous material. We would expect, also, to find the abdomen greatly distended and all the symptoms of marked strangulated hernia. There would be symptoms of an irritated condition of the peritoneum and more or less effusion of the peritoneal cavity; in the absence of special symptoms, the general symptoms of a developing peritonitis. I do not believe this is a hernia, as we can feel the opening and can

apparently separate it from the mass to one side, the latter inference would seem to be justified.

If it is not a hernia, what is the condition? The redness of the surface, the size of the mass, its tenderness, would lead us to believe that we had an acute inflammation, with development of an abscess. It may be interesting to determine why we should expect an abscess in this situation. It is not unusual to find that points of induration in the abdominal walls following an operation, may break down and suppurate. This may have been the explanation in this case. I do not propose, however, to make an opening at once into this, even though it presents all the symptoms of an abscess, as it would be very unjustifiable to risk such a procedure unless we are absolutely certain that we have excluded the possibility of hernia, as every measure should be exhausted that would favor such elimination. So prior to opening this cavity I shall make a puncture with an exploring needle and see if we can obtain pus. Thoroughly cleansing the surface and having a clean instrument, I make this puncture and do not find, as I had expected I might, any indication of pus. There is a free discharge of blood, showing there is some congested tissue within. Having relieved the congestion through this puncture, by manipulation I find I am able to dislodge a small mass from the cavity here, and this mass can be pushed back through the ventral opening, so we have had a hernia, not of a knuckle of intestine, but of a portion of the omentum, which has been so firmly forced into the abdominal walls as to give rise to this painful tumor and to the presence of external redness.

You can now appreciate the importance of having exercised the precautions that are done to avoid the possibility of any error. Had I proceeded upon the theory that this was an abscess and made an opening, I would have injured the omentum, rendered its return a source of danger and might possibly have injured a knuckle of intestine. So in every procedure of this kind, even where you feel there is reasonable certainty for your assurance, leave no means of completing your diagnosis unused, but resort to operative procedure. The puncture with the exploring needle, even though it may have been a knuckle of intestine, would not have had any injurious effect. It would have merely permitted the escape of any retained gas and by decreasing the size of the protruding mass would favor its reduction.

A compress will be placed over this opening to prevent the further escape of bowel or omentum. The patient should either be subjected to radical operation for the cure of the hernia, or directed to wear a pad or truss that will prevent its further escape. In addition to the difficulty of diagnosis in this case, it is of particular interest from the fact that the gentleman who has operated upon her twice, is one who claims to be particularly free from the accidents and sequelæ of abdominal surgery, and lectures in very strong terms his colleagues who are engaged in similar practice, for their failures, citing them as evidences of bad surgery. She underwent two operations; in the first place for removal of pus tubes, and second, for relief of ventral hernia. She still has a hernia in which there has been a portion of the omentum pushed out and pushed into the abdominal wall between the muscle and superficial fascia. This condition is one which may occur in spite of every precaution. Ventral hernia is so undesirable that we endeavor in every way to obviate its occurrence, yet in spite of all measures we take, it does occur. The gentleman who has operated upon this patient twice, is a man of large experience, a man of ability, a careful surgeon, and the mere fact that he has done the operation is an indication that every measure which could have been exercised has been employed to prevent this occurrence.

Fibroids of Uterus.—The next patient is 27 years of age, puberty occurred at 15, with no unpleasant phenomena. She has been married three years, had one miscarriage after two and one-half months gestation and was confined to bed subsequently three months; now complains of pain during menstruation which lasts ten days; has severe pain in the left side, fever, nausea, vomiting, with constipation of the bowels. The points in the history of this patient are, that menstruation lasts ten days, is quite profuse, and taken in association with the color of the individual, leads us to suspect the possibility of some growth about the uterus. Of course it is not impossible

that this hemorrhage may be a result of conditions resulting from retained products of abortion. As I introduce the finger into the vagina I find the cervix directed anteriorly; passing the finger posteriorly it comes in contact with the posterior surface of the uterus, which may be followed out on the right side of the patient. On the left side there is a rounded mass which projects against the posterior wall of the vagina, is closely associated with or attached to the side of the uterus, and has pushed the latter organ toward the right. This mass fills up entirely the left side of the pelvis. It is evidently not of inflammatory character. We are led to this supposition by the fact that this uterus seems to be impacted in the pelvis, that it is not movable. The mass to the left, while rounded, is very resistant and firm, and the fingers can be passed over it; there is no melting away of the mass into the tissue around it as would be the case in an inflammatory condition. In other words, the mass is defined and limited. While it fills up the pelvis it has a definite shape of itself, and is not merely a mass of inflammatory exudation. Of course we could have a mass in the tube and ovary, the result of inflammation, containing pus, but in such a case we would find there would be more or less inflammatory exudate around it, so the tissue would be hard, difficult to define and limit. In this case the mass is round, closely attached to the uterus, fills up the left side of the pelvis, pushing the organ to the right. I am inclined to believe this to be a fibroid. This, however, is still further increased by the fact of the color of the patient. She is a colored woman and in this race there is an increased tendency to development of such growths. This growth, evidently situated in the broad ligament on the left side, has grown down into the pelvis, pushing the uterus upward and over to the opposite side. The pressure of the mass would give rise to interference with the circulation of the pelvis and increase the tendency to hemorrhage. Whether it is inflammatory or a growth, we would be likely to have hemorrhage. In this patient the only plan of treatment of any service would be operative, and we cannot expect that medicinal treatment would be of much service to arrest its growth or allay the symptoms from its presence. The operation would be removal of the uterus. This might be attended with some difficulty for the reason that such growths developing into the broad ligament, sometimes spread it out, and if they develop low down they lift up the ureter and bladder, and greatly increase the danger in their removal; indeed, in some cases so intimately connected does the ureter become that it is difficult to remove the growth without injury to that duct.

Cancer of the Vagina. The next patient is a woman upon whom we operated some time ago on account of an induration which involved the anterior wall of the vagina and the orifice of the urethra. As I separate the vulva you notice upon the right side and in front a raw surface, a mass of induration which extends up the anterior wall of the vagina nearly to the uterus. We attempted an operation with the hope that we might be able to remove the disease and arrest its growth, but found it involved the entire anterior wall of the vagina and the surface of the bladder to such a degree as to preclude the possibility of its removal. The lower part of the urethra broke down entirely at the time, so it left simply the ring at its upper part, through which the finger was introduced, disclosing the extent of the disease. The operation at that time gave great relief, as it facilitated the more ready evacuation of the bladder and relieved her from the distress and pain attending it. If we were so situated as to be able to accomplish it with safety, this patient would be a good one upon whom to try the influence of injections of the poison of erysipelas. This plan of treatment has seemed in some cases, more particularly, however, in those of sarcoma, to arrest the growth and facilitate the relief from the disease. It is not a plan of treatment we could pursue with safety in a general hospital, and as we have but one ward for treatment of such cases in this institution, we cannot try it.

Carcinoma uteri.—The next patient is thirty-eight years of age; married; had nine children, one miscarriage; complains of hemorrhage; almost constant discharge from the uterus; has lost weight; has severe pain in the lower abdomen; bowels are constipated; has pain on urination; poor appetite. As I separate the vulva I find a bloody discharge; as the finger is introduced into the vagina it comes in

NEURASTHENIA FROM MALARIA.

Dr. Triontaphyllides (*Deutsche Medizinai-Zeitung*, No. 2, 1895) claims that among the various manifestations of malaria, which have not been noticed nor described sufficiently, may be observed neurasthenia. The patient may present no other malarial symptom. During the past four and a half years he has observed about fifty such cases, and the malarial basis he has been able to demonstrate by finding the hematozoa and by the therapeutic test with quinine. In the mildest forms only apathy and psychic malaise are noticed. In the gravest forms all the psychic, vasomotor and other characteristic symptoms may be observed. Sleeplessness, headache and disturbances of digestion are, on the contrary, less constantly observed than in ordinary neurasthenia. Quinine subcutaneously generally brings about a recovery.

A LOCAL APPLICATION FOR URTICARIA.

In *L'Union Medicale du Canada*, No. 10, 1894, for the treatment of urticaria the following local application is praised:

Lime-water	} āā
Cherry Laurel water.....	
Glycerine	

Apply locally and cover the skin with a thin layer of cotton.

IODOFORM INJECTIONS IN GOITRE.

Prof. Garrè (*Centralblatt Fuer Chirurgie*, No. 52, 1894) has, during the past two and a-half years, treated at the Tuebingen Surgical Clinic, one hundred and forty cases of goitre by parenchymatous injections of a solution of iodoform—Mosetig's method—and the results were so brilliant that he warmly recommends it. The patients all remained at their respective occupations. The following solution was used:

Iodoform.....	1	oo (grs. xv).
Olive Oil.....		
Ether.....āā	7	oo (℥j. ¼).

At times a 5 per cent. solution of the drug in oil of sweet almonds was used. He generally injected not more than a hypodermic syringeful at a sitting, though he has injected two to three, or even four ccms. into different portions of the growth at the same time. They were made every two to five days, rarely every day and not infrequently every eight days. No disagreeable symptoms were noticed to follow. The total number of injections varied between three and sixteen; out of fifty cases he deduced seven as an average; with a medium period of treatment of three to four weeks. Out of eighty-seven cases the final results were: In fifty-one decided decrease in size; in twenty-six slight diminution of the circumference of the neck; and out of eighty-seven cases in seventy a result was obtained. In about forty he could confirm the permanency of the result after one to one and a-half years. Soft goitres are best treated in this manner.

FETID DIARRHŒA IN CHILDREN.

In *L'Union Medicale du Canada*, No. 10, 1894, for the fetid diarrhœa of children, the following formula is spoken of highly:

Calomel.....	grs. jss.
Sulpho-carbolate zinc.....	℥i.jss.
Subnitrate bismuth.....	℥i.j.
Pepsine.....	grs. xxx.

Twenty powders. Three per diem for a child of one year.

Albuminuria, Casts and Bright's Disease.

Shattuck (*Boston Medical and Surgical Journal*), has examined the urine of patients seeking his advice for various ailments. He has used boiling with additions of nitric acid and the Heller test, and considers them the most satisfactory.

He concludes his article as follows:

(1) Renal albuminuria, as proved by the presence of both albumin and casts, is much more common in adults quite apart from Bright's disease or any obvious source of renal irritation than is generally supposed.

(2) The frequency increases speedily and progressively with increasing age.

(3) This increase with age suggests the explanation that the albuminuria is often an indication of senile change.

(4) Though it cannot be regarded as yet absolutely proved, it is highly probable that faint traces of albumin and hyaline and finely-granular casts of small diameter are often, especially after 50 years of age, of little or no practical importance.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, MARCH 2, 1895.

EDITORIAL.

AN OVERCROWDED PROFESSION—THE SUPPLY OF PHYSICIANS.

Dealing with the general law of demand and supply in its bearing on the American medical profession, we have shown that the profession is certainly liable to the operations of ordinary economic laws, and that the demand for medical services has been lessened by the efficient enforcement of sanitary measures and by the growing popular appreciation of practical hygiene. We may add that the radical surgery of modern times has relieved a large number of chronic invalids; most of them having been cured, a few having succumbed to shock.

According to the Physicians' Directory, there are several New England towns of from five to ten thousand inhabitants, with not more than one physician per thousand of the population. But these towns are, for the most part, suburbs of cities in which the rate is much higher. Horace Greeley's advice to young men to "Go West," can scarcely be followed by the young doctor, for, in many Western towns the ratio of physicians to the total population is 1 : 300, or even 1 : 200. These towns, however, are manifestly health resorts with a relative excess of invalids, including not a few physicians who are fighting tuberculosis, chronic rheumatism or some other ailment in their own persons, and endeavoring, at the same time, to earn part of their expenses.

The total population of the United States and Canada, practically united so far as our subject is concerned, is about 70,000,000. This population is supplied by a profession of between 140,000 and 160,000. As this number probably includes many who are only nominally in practice, the actual practitioner can count on an average clientage of about 500 or, perhaps, 600.

The population is increasing at the rate of about a million yearly, so that, without increasing the ratio, about 2,000 members may annually be added to the profession. Moreover, the death-rate of medical men,

25.5:1000, causes an annual depletion of our ranks to the number of 3,500. Thus, there is the nominal demand for the graduation annually of 5,500 students.

From figures quoted in the *Journal of the American Medical Association*, it is gathered that the number of medical students in the United States and Canada is about 20,000, of whom, let us say, 6,000 are in the graduating classes, whether the schools require two, three, or four years of study. So far as personal observation warrants, we should estimate that about 90 per cent of all aspirants are graduated. Undoubtedly, the smaller and poorer colleges—poorer in a double sense—rarely have the courage to "pluck" a student, but colleges of high grade sometimes reject at the final examinations as much as twenty per cent. of the class. These figures show that, if not actually increasing, the supply of doctors fails to respond to the diminishing demand.

It must be remembered, also, that there are many practitioners of medicine to be considered in an economic study, who would be ignored in professional records; and that while it is comparatively easy to obtain accurate reports from the better class of medical schools, there are diploma-mills and schools that are legally but not educationally qualified, from which it is impossible to get reliable information.

We believe it may safely be concluded that while the absolute ratio of the numbers of the profession to the total population is nearly stationary, the output of the medical colleges is in excess of the constantly decreasing demand, and that harder and harder times are in store for the profession unless some efficient remedy be found to check the evil. This brings us face to face with an issue between the welfare of the whole profession and that of the medical colleges; an issue of such importance and complexity that special consideration must be given it.

ABSTRACTS.

CASTRATION FOR SENILE HYPERPLASIA OF THE PROSTATE.

This subject was first brought forward at a meeting of the American Surgical Association in a most complete and suggestive essay by Dr. J. William White, of Philadelphia, published in Vol. XI of the *Transactions*, p. 167, sqq., 1893. After a most exhaustive review of the literature of prostatic enlargement, the author dealt with the present position of surgery in regard to its treatment, entering fully into the various operative procedures that have been from time to time recommended either for its relief or permanent cure. A short account of the development of the bladder and prostatic portion of the urethra was given, and reference made to the analogy first pointed out by Velpeau, and subsequently emphasized by Sir Henry Thompson, between uterine fibro-myomata and the so-called "prostatic hypertrophy." Dr. White's attention was further drawn in this direction by the observations of John Hunter on castration in the bull, in which he found, as the result of the operation, that the prostate from being "soft and bulky" became "small, flabby, tough and ligamentous."* Similar results in other animals were recorded in a paper published by Dr. Joseph Griffiths in the *Journal of Anatomy and Physiology* for 1890. While Dr. Griffiths' paper was primarily written with the object of proving that the prostate is in its essential significance a sexual and not a urinary organ, he in it incidentally alluded, as part of his case, to the effects that re-

* Hunter does not explain in his remarks how an organ can be "tough and ligamentous," and at the same time "flabby." Perhaps we must excuse a little looseness in the use of qualifying adjectives.

sulted from castration in eunuchs, dogs, cats, pigs, bullocks, sheep and horses. "'The behaviour of these accessory sexual glands" (*i.e.*, the prostate), he writes, "after the removal of the testes will, I think, enable us to decide whether, on the one hand, they are developed in relation to the generative function, and entirely owe their existence to the generative stimulus, or, on the other hand, whether they arise independently of the testes and are essentially developed in functional relation to the urethral, and serve to produce a secretion which has for its purpose the moistening of that channel."* The results of Dr. Griffiths' observations went entirely to prove the former hypothesis, and he found in all the cases of castration in these animals considerable diminution in size of the prostate gland with marked atrophy of its grandular and muscular elements, only traces of the former being left as islets amid dense bands of fibrous connective tissue. These observations were strengthened by cases previously published by Gruber and Bilharz showing the results on the prostate produced by castration in men.

Arguing then from these two postulates—1st, That the "growth, or growths, which made up the enlargement in prostatic hypertrophy, are analogous to those fibro-myomata so frequently found in the uterus," and if so the results of castration ought to be similar to those observed to follow oöphorectomy in the case of the uterine growths; and 2d, That the recorded evidence in man and animals showed a decided shrinking of the prostate gland to be one of the constant results of castration; Dr. White instituted a control series of experiments in dogs as a preliminary to the adoption or suggestion of castration as a surgical procedure in these cases of senile enlargement of the gland. Thirty-five dogs and their prostates were weighed, and the average weight—15.37 gr.—was taken as the standard. Dogs were then castrated and killed at varying intervals, and the prostates were carefully examined both macroscopically and microscopically. The results obtained were striking. In every case, even much sooner than was anticipated, there was a marked and rapid decrease in the size of the gland, associated with a diminution in weight of from 15 to 2–4 grams. At the same time it was found microscopically that there was an almost complete atrophy of the glandular and muscular elements, the glandular suffering first and most markedly. Hence, as the result of these experiments, and of the evidence very briefly reviewed above, Dr. White thought himself justified in at least suggesting operation in suitable cases, and put forward these two propositions:—

"(1) Does the evidence warrant us in believing that castration in cases of hypertrophied prostate would be followed by a disappearance or diminution of the growth?

"(2) If so, is it likely that the fact can ever be taken advantage of as a therapeutic measure?"

Naturally Dr. White's somewhat revolutionary and revulsive proposal was provocative of much discussion, and an answer to his second question was not long in forthcoming. As the subject is only in its infancy, and anything that throws light on it is at once helpful and instructive, a brief summary of all the recorded cases is here appended:—

Cases I. and II.—Ramm (*Centralblatt f. Chirurgie*, No. 35), operated in April, 1893, on two cases with the most encouraging results, as he reports so marked an improvement as to amount to a practical cure in both cases.

III., IV., V.—Haynes of Los Angelos, California, reports in March, 1894, three cases operated on in December, 1893. The first case was of two years standing; symptoms apparently not very severe; cured. The second was a bad case which required catheterism every two hours, in addition to which the patient had contracted the morphine habit in order to obtain relief from his intolerable sufferings. The cystitis was extreme. Results: Cystitis cured; catheter only necessary four or five times daily; complete recovery from morphinism, and marked improvement in general health. The third case was one in which the disease was in an early stage, but on account of the peculiar conformation of the prostate catheterism was impossible. The result was a complete cure.

It may be mentioned here that in one additional case Haynes, as an alternative measure, performed section of the vasa

* Loc. cit., p. 32.

deferentia, but without any alleviation of the symptoms. This is interesting in connection with a case in which Mr. Reginald Harrison, though strongly urged by his patient to perform castration, temporised by performing ligature of the vasa deferentia, and although the patient was alive several years after the operation, and reported "well," no details are given as to the condition of the prostate gland."*

VI.—Dr. F. Smith, of Florida, operated on a very extreme case of prostatic obstruction, with bad cystitis. Fifteen weeks after the operation the cystitis was cured, urination was normal, and the patient had gained forty-five pounds in weight.

VII.—Dr. J. W. White, Jan., 1894. —In this case there was intense cystitis, all the urine being passed by the aid of a catheter and extremely offensive. The prostate was the size of an orange. Fourteen weeks after the operation the prostate was reduced to its normal size, and the urine was normal in every respect, but the power of emptying the bladder had not up that period been regained. Further details of this case are wanting.

VIII.—This case, operated on by Dr. Powell, hardly comes within the true category of these we are considering, as the operation of castration was performed for a totally different cause. It was, however, followed by complete relief of the symptoms due to prostatic enlargement.

IX.—Mayer, in May, 1894, operated on a man, aged seventy, with cystitis, ammoniacal urine, tenesmus, and toxæmia, in whom catheterism was rapidly becoming impossible on account of pain and the size of the growth. Three weeks after the operation the urine was nearly normal in character, and the prostate was dwindling in size. Six weeks after operation the prostate had shrunk to its normal size, and the bladder was able, unassisted, to completely evacuate its contents, no catheter being used.

X.—Mansell Moullin reports a case in a man aged eighty-one, for whose relief supra-pubic aspiration had been several times called in requisition. After castration the improvement was immediate. In ten days the prostate was appreciably smaller, and in three weeks it had "practically disappeared." The bladder had begun to regain power, and the urine was nearly normal.

XI.—Thomas reports a case of fifteen years' standing, the patient being sixty-five years of age. There had been considerable distress before the operation, and after it there was considerable improvement, the patient only requiring to urinate three times a day. This case is very meagre in its details.

XII.—This case is reported by Dr. Ricketts. The patient was seventy-four years of age, and had suffered for some time. Improvement followed the operation almost immediately, the patient stating he had not had such ease for a year; he could sleep for four hours at a stretch, whereas formerly he had been compelled to get up every hour or oftener, micturition being necessary about thirty times daily.

XIII.—The last case on our list is only reported in the *British Medical Journal* of January 5, 1895, by Mr. Swain. The patient was seventy-three years of age, and had suffered for five years from prostatic obstruction. Catheterism became impracticable, and as a last resort castration was performed. Three weeks after the operation a perceptible diminution in the size of the prostate was noticed; "but in the third, fourth, and fifth weeks the increasing atrophy appeared to

*Meyer (Annals of Surgery, July, 1894), describes a case in which he ligatured the internal iliac arteries (Bier's method) for hypertrophied prostate in a man aged fifty-five, who had had marked urinary trouble for over four years, and whose urine was purulent. Twelve hours after the operation the patient passed urine voluntarily for the first time within six months. There was marked atony of the bladder, yet continuous retention never set in again. The prostate became smaller, and the length of the urethra became reduced from 23½ to 21½ centimetres in six months (B. M. J. Supplement, August 18, 1894). It may here be mentioned that in the discussion which took place on Dr. White's paper at the meeting of the American Surgical Association, Dr. J. Ewing Mears, of Philadelphia, suggested the alternative procedure of ligaturing the vasa deferentia. Dr. Mears further read a paper on this subject before the Philadelphia Academy of Surgery in November, 1894, (MEDICAL AND SURGICAL REPORTER, December 15, 1894) advocating this procedure as an alternative mode of treatment in extreme cases of hypertrophied prostate, and urging that it was applicable in these cases where patients had a sentimental repugnance to castration. We do not see the difference, from a psychological point of view, between producing impotence by ligature of the vasa deferentia and by castration, and moreover, from the surgical point of view, we have yet to receive evidence as to the benefit of ligature, as those cases in which it has been tried hitherto have yielded none or negative results so far as the prostatic disease was concerned.

progress more rapidly. . . At this time his general condition had much improved; his urine was normal—he sometimes passed half a pint at a time—but he could not hold his water for more than four or five hours in the daytime. There was no 'residual urine' in the bladder." The prostate meanwhile had diminished from the size of an orange to that of a large horse chestnut. Thirteen weeks after the operation the prostate was still smaller and firmer; the patient was able to dispense with a catheter, and did not require to get up at night to pass water; and the urine had completely returned to its normal characters. There was no cystitis.

These cases—all on record up to the present time—certainly form a striking object-lesson in the treatment of this most distressing of all the surgical complaints to which old age is liable. So far, it must be admitted, the results are encouraging. The strongest objection to the operation appears to be the sentimental one. But few healthy-minded men will, we imagine, object to the removal of appendages which have long ceased to be useful, when weighed in the balance with the life-long misery and torture caused by prostatic enlargement. It is only those who are the victims of a *psychopathia sexualis* who will preserve the reminiscences of past virility at the cost of a present and future bodily and mental enfeeblement. As Dr. White justly observes in summing up his remarks:—"There will be no lack of cases willing to submit to an operation almost painless, with a low mortality, and followed by no such unpleasant conditions as accompany persistent fistulous tracts, either supra-pubic or perineal, even although the operation carries with it the certainty of sacrificing whatever sexual power has survived the excessive, and often intolerable, suffering of such patients.—*Dublin Journal of Medical Science.*

ON THE TREATMENT OF ACNE COMMUNIS.

One of the most common diseases of the skin in San Francisco is acne communis. It is due, apparently, to the dusty streets and to the inferior sanitary conditions in general of the city. It is a great deal more frequent among women than men, especially among women between the ages of 13 and 20.

The acne is secondary to the comedo, the latter being an accumulation of sebum at the mouth of the sebaceous duct, the duct probably being plugged up by particles of dust, soot, etc. This comedo acts as a foreign body and produces the acne. Our first duty is to prevent the formation of the comedos, for in doing this we also prevent the acne. Applications of soap, as generally used, seem to have an injurious effect on faces predisposed to comedo and acne, their action being to remove the upper layers of the epidermis and to expose the ducts of the sebaceous glands. The treatment is first to remove as much as possible by a mechanical process, with the comedo expresser, the comedo, and apply adstringent lotions and ointments. The treatment of acne should aim to denude the surface of the acne pustule, either with a lancet or with alkaline remedies and remove its contents.

When a patient comes to me for treatment, the first remedy given is: Spirit. saponato, kalin ℥iv. Sig. Externally. A few drops are applied to a piece of flannel moistened with luke-warm water and applied several times a day. After drying the face thoroughly, the following ointment is used: Past. resorcin 3 per cent; to be applied both day and night. If necessary (where the patient has a tendency to emaciation,) a tonic is given consisting of: Elix. cinchon, ℥iv; liq. gude; syrup hypophosphite, comp., aa ℥j. A tablespoonful three times a day before each meal. This treatment will baffle, if properly carried out, almost any case of acne.—*Pacific Med. Jour.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY

for December.

Eugene Boise, M.D., of Grand Rapids, Mich., contributes a paper on

Suppression of Urine After Abdominal Section.

The author questions whether ether should be classed with other irritants of the kidneys, such as cantharides, and considers that the case is not proved. "The difficulty in forming any opinion which might be regarded as conclusive lies in the fact that when ether is used for operative purposes, other factors enter largely into the case which render conclusions as to the influence of the ether in the causation of any consequent urinary disturbances fallacious." In a number of cases he had made a careful analysis of the urine previous to operation, and of the urine drawn immediately afterward, care being taken to draw directly into a bottle, which was securely corked at once. "In all cases there was a strong odor of ether, and in nearly all cases there was a transient trace of albumen, often very slight. The color was somewhat darker than usual, and the amount greatly lessened during the first twenty-four or forty-eight hours, gradually thereafter returning to the normal." In no case could he perceive any influence on the secretion of urine which he could positively say was due to the action of ether.

We have as factors in the causation of suppression of urine after abdominal operations:

First, the direct irritation of the abdominal vessels by the mere opening of the abdominal cavity, aggravated to a greater or less extent by the more or less severe reflex irritation of the renal plexus by injury to other parts of the abdominal sympathetic.

Second, that condition known as shock in which the contraction of the renal and other abdominal arteries exists conjointly with general arterial contraction and consequent venous engorgement. In such cases there is not only lowered blood pressure in the renal arteries, but retarded velocity through the renal capillaries because of venous obstruction.

Third, the direct depletion of the blood and consequent lowering of the blood pressure by the removal and withholding of fluids.

Fourth, the problematical irritant effect of the anesthetic.

The indications for treatment are: First, to avoid the possible irritant effect of ether by refraining from saturating the patient beyond the point of necessary anesthesia. Too little attention is paid to this point.

Second, to replenish the blood vessels by the free administration of hot water. As the water cannot of course be given by the mouth, the author prefers to give it by the rectum, because: First, the water is rapidly absorbed, easily retained, and comparatively painless; and second, it brings the soothing effect of heat almost directly to the renal and solar plexuses, thus greatly aiding in allaying irritation and relaxing arterial spasm. To fulfill this indication, it is necessary that the water should be hot rather than merely warm. For this reason also the rectal is to be preferred to the subcutaneous use of water.

He regards this use of hot water as of very great benefit in the treatment of threatened or existing suppression, and now almost invariably directs its use immediately after every abdominal section unless there is some special contraindication.

The treatment of the arterial contraction, by which the amount of blood carried to the kidneys is lessened, should be by arterial relaxants, chief among which are codeine and nitro-glycerine (aided, perhaps, later by pilocarpine.) He prefers codeine to morphia on account of its freedom from nauseating and constipating effects. When the renal arteries are in a state of unnatural contraction by reason of irritation of their vaso-motor nerves, codeine, by its sedative action allays the irritation, relaxes the spasm and restores the blood current through the kidneys to its normal condition.

Denslow Lewis, M.D., Gynecologist and Obstetrician to the Cook County Hospital, Chicago, writes of

The Injurious Effects of Pessaries.

After detailing some of the various ill effects of pessaries, he says: "My experience with pessaries during the past ten years has consisted solely in their removal. Some form of the Alexander operation, the operation of colporrhaphy, perineorrhaphy, trachelorrhaphy, hysterorrhaphy and in a few cases hysterectomy—singly or combined, according to the requirements of each individual case—have sufficed in my experience and that of my assistants to control all displacements of the uterus, as well as all inconveniences occasioned by them." He, however, does not think that the pessary should be entirely banished as there are cases where the judicious use of the instrument is capable of much good. "The physician who inserts a pessary should, however, realize its powers for evil as well as good. He should insist on frequent examinations; he should be on the alert for the possibilities; he should remember that deviations of the uterus have not the importance that was attached to them twenty years ago; he should remember that the inflammatory conditions of the tubes and ovaries frequently cause a prolapse of these organs into Douglas' *cul-de-sac*, and, that eminent gynecologists to-day do no hesitate to assert

that cases of so-called retroflexions of the uterus are all of them really tubes or ovaries often bound down by adhesions behind the uterus. These facts should be remembered by every practitioner, and he should further understand that a pessary, if suitably applied, causes relief and not distress. In case the patient complains of sensations of pressure or of other inconveniences, the possibility of incorrect adjustment or improper application should not be forgotten. Above all things the patient should be instructed in the care of the pessary. It should be remembered that she carries in her vagina a foreign body which requires attention. At suitable intervals it should be removed, cleansed and disinfected, and the opportunity should be utilized to ascertain the benefits or injuries occasioned by its use. The vagina should be regularly and systematically douched, not alone to disinfect the parts, but also to remove the excess of secretion resulting from the presence of the pessary. These measures are easily carried out in private practice. In hospital, and especially in dispensary practice, they are impracticable, as a rule, and for this reason, if for no other, the pessary should, in my opinion, be rarely advised in such cases."

Dr. Herman E. Hayd, of Buffalo, presents the "Report of Two Cases of Extra-Uterine Pregnancy. Operation—Recovery."

The editorial in this issue is on "The Dangers and Results of Symphysiotomy."

In the department of Pædiatry. Charles Greene Cumston, M.D., contributes a paper on

The So-called Idiopathic Purulent Peritonitis in Children.

The author believes that idiopathic peritonitis is commoner in infancy than in adults. "As to the terms of idiopathic or essential purulent peritonitis of children, they only signify that it is not due to perforation of the intestine or appendix or to tuberculosis. When these two great classes of peritonitis are eliminated we are in the presence of a doubtful and uncertain etiology, but one which bacteriology is clearing up, and it is only a question of time before cold, etc., will be put aside as a cause and something definite found."

THE AMERICAN JOURNAL OF OBSTETRICS

for January.

H. J. Boldt, M.D., Professor of Gynecology at the New York Post-Graduate Medical School and Hospital, etc., contributes an article on

Vaginal Extirpation of the Uterus and Adnexa in Pelvic Suppuration and Septic Puerperal Metritis and Peritonitis.

The author argues that if there is sufficient disease present to justify the removal of the appendages the uterus should be removed as well. The cause lies in and about the uterus. For this reason so many women are unrelieved after the removal of infected tubes and ovaries. The author pleads for this method of operating in the bad cases, as in those there is the necessity for drainage and in consequence there is the danger of a subsequent hernia in the site of the drainage tube. By the vaginal method all drainage is per vaginam and there is therefore no danger of hernia. He also maintains that there is less risk of intestinal adhesions by the vaginal method and that there is no more risk of intestinal obstruction than in abdominal section; and, as his experience has thus far shown, the remote dangers are *nil*. There is less traumatism and exposure of intestines in the vaginal method and the danger of contamination of the general peritoneal cavity with septic material and its dissemination is practically *nil*. If a pus sac is opened per vaginam the contents flow down and out according to the law of gravity; the intestines very rarely come in contact with pus, but should they, there is no possibility present of the septic material spreading, as is the case when enucleating or opening pus cavities per abdomen. The duration of convalescence he also claims is greatly shortened and he states that it is the rule for patients to be out of bed within a week.

In simple pelvic abscess he advocates the operation of vaginal incision and drainage.

His conclusions are that the removal of the uterus and adnexa for bilateral disease of such extent that both appendages must be sacrificed, as ascertained by the history and examination, is preferable to the abdominal operation, on account of the more favorable immediate and remote results. That it is more logical to expect a favorable termination from vaginal hysterectomy in acute puerperal septicemia and septic peritonitis, if the uterus be the causative factor of the poisoning, than from abdominal salpingo-oophorectomy with flushing and drainage of the peritoneal cavity.

A. Palmer Dudley, M.D., Professor of Gynecology in the New York Post-Graduate School and Hospital, etc., discusses

The Technique of the Cæsarean Section.

The author believes that the long incision of the abdominal walls with subsequent turning out of the uterus before opening it, adds to the risk of the operation, and instead uses a six inch incision, extending from a point one and a half inches below the navel to within an inch and a half of the pubic bone. The hand and forearm are then introduced through the incision and swept about the uterus to note the position of adhesions, should they by chance exist. A loop of elastic cord is then quickly carried through the incision, over the fundus of the uterus and down to the cul-de-sac behind it, the ends of which are given to an assistant who makes steady traction upon them, thus holding the uterus against the pubic arch. This cuts off the blood supply from the uterus and prevents hemorrhage and also prevents the leakage of amniotic fluid, and acts as an assistance in delivering the uterus through the abdominal incision as the child is being delivered from the uterus. The uterus is then quickly incised along its anterior surface

without regard to the position of the placenta, until the fetal sac is reached. During this procedure a second assistant makes firm pressure upon the abdominal walls from above downward and forward, his duty being to hold the upper portion of the uterus firmly against the abdominal incision; as the child is being delivered he gradually presses the uterus out of the abdomen through the incision as it contracts upon itself. All this is done under constant irrigation with hot boiled water.

The author is indifferent as to the position of the fetus, delivering that portion of the child which first presents through the incision.

The author advocates the use of a continuous catgut suture in closing the uterine wound. After the child has been delivered, and while the placenta is separating, the uterine cavity is irrigated with hot bichloride solution, 1:5000. Still continuing the irrigation, the uterus is closed with three rows of catgut sutures used as a continuous stitch; the first row beginning at the inner edge of the upper angle of the incision and including the decidua and inner muscular coats of the organ. This row of sutures is continued to the lower angle of the incision under irrigation, and when drawn together they close the uterine cavity. Without cutting or tying the catgut the second row is carried back to the upper angle of the uterine incision, including the various layers of muscular structure and uterine sinuses, care being taken to pass the needle through the cut extremities of all the sinuses that are visible. By these two rows of sutures three-quarters of the depth of the uterine structures have been brought into close opposition and both layers of sutures are buried; while the third and last row of sutures must close the peritoneal surface of the uterus and are not completely buried, but, without cutting the catgut, the stitch is inserted so as to allow it to just appear on the peritoneal surface of the uterus, the over and-over stitch being continued from above downward until the suturing is complete and the catgut tied at the lower angle of the incision. When this has been completed the constricting elastic cord is removed and the circulation allowed to resume. The abdominal incision is then closed with three rows of sutures, two of catgut.

The author believes in the elective operation, fixing the date of operation at least four or five days previous to the expected time of natural labor.

If possible chlorotorm should be administered in preference to ether, as the rapidity in bringing the mother under the influence of the anesthetic is quite essential to the well-being of the child.

"Bicycling for Women From the Standpoint of the Gynecologist"

is the title of a paper by Robert L. Dickinson, M.D., Lecturer on Obstetrics and Obstetrician to Long Island College Hospital, etc. The author gives this summary of his views: "Under proper conditions of costume and posture, with care that the exercise be gradually increased and properly graded for the individual case, and where there is no acute inflammation to contra-indicate it, bicycling will probably show itself capable of large results as an agent in curing pelvic disorders, since it is one of the few exercises which attract women.

"In view of women's disabilities, and the disadvantages which she has suffered in attempts to obtain interesting and beneficial muscular exercise, it seems hardly too much to say that the promise from bicycling is far-reaching. Through it and the habits it will engender we look for better dress, freer dress, shorter dress in bad weather; for better exercise, for out-of-door activity, for steadier nerves, stronger muscles, painless periods, easy labors."

The author denies that there is any sexual excitement produced if the saddle used is properly made and properly fitting.

The remaining papers in this issue are:

"Pelvic Massage in Gynecology." By W. H. Rumpf, M.D., Chicago, Ill.

"Restoration of Intestinal Continuity without Mechanical Devices." By W. E. B. Davis, M.D., Birmingham, Ala.

Calomel.

To remove obstructions, promote absorption, stimulate and correct the secretions and give new vigor or tone to the entire digestive and circulatory apparatus, Daughton uses a formula somewhat as follows:

Calomel	60 gr.
Powdered socotrine aloes	10 gr.
Rhubarb	15 gr.
Powdered columbo	10 gr.
Powdered cloves	5 gr.

Make 60 pills and give 1 every 2 or 3 hours until the stools are bilious, *i. e.* black, glistening and tarry-looking.—*Southern Practitioner.*

Pleasant Laxatives.

Every physician has felt the want of a pleasant purgative for children. Dr. C. H. Smith writes to the *Columbia Medical Journal* that the following formula has been used by him for years:

Glycerine	ʒj.
Ol. cinnamon	gtt. vj.
Trit. ben et adde Ol. ricini	ʒi.

M. S.—ʒj at a dose p. r. n.

For chronic constipation Dr. Delafield prescribes the following pill:

Strychniæ sulph	gr. 1-40.
Ext beladonna Pulv. ipecac Ext. colocynth co	gr. ¼.

M.—Ft. pill No. i.

Sig.—Four pills daily at first; then three and afterwards two.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Technique of Making Urethral Injections.

Guiard (*Annales des Maladies des Organes Genito Urinaire,*) gives the result of his investigations concerning the urethra and its medication. The capacity of the urethra had been stated by Jarmin and Leprevoct to be from five to eight gramms, therefore it was held that a urethral syringe should not hold more than five or six gramms, equal to about one and a half drachms. Later it was shown that posterior urethritis, particularly late in the disease, was far more frequent than was formerly supposed. The author by experimenting in the living subject found that the urethra would always hold eight to ten gramms (two to two and a half fluid drachms,) and more often twelve to fifteen grammes, and sometimes sixteen to seventeen. As the patient could tell when the sphincter was forced, this was avoided. These deep injections are only called for when definite symptoms have already demonstrated that the posterior region of the urethra is already affected.

In order to administer these deep injections the author uses a syringe of twenty gramms (five drachms) capacity. When it is desired to overcome the sphincter, gentle pressure is made when the liquid will enter. In an experience of ten years he has never had any accidents, and only encountered one case in which the sphincter would not relax. It is better to give the injections when the patient is lying down than when he is standing up. The requirements of an effective injection is that is shall reach the diseased parts. To do this a syringe of twenty gramms (five fluid drachms) capacity should be used, and the injection of its entire contents, if carefully done, is easy and causes no inconvenience.—*Univer Med. Mag.*

Ingrowing of Nails.

Ingrowing nails, or *ongle incarne*, as the French call it, is, as is well known, a very painful affection, and unfortunately, the operation necessary for its cure is often dreaded by the patients, although local and general anesthetics are employed to render the avulsion as painless as possible. A very simple method has been frequently employed by a *confrere* with constant success. It consists in painting the offending portion of the nail with a warmed 40 per cent. solution of caustic potash. In a few seconds the upper horny layer is rendered so soft that it can be easily removed by a piece of broken glass used as a scraper. The application of the solution and the scraping is continued until nothing but an exceedingly thin portion of the nail remains, which can be easily removod by a small scissors. The patient can now be considered cured, without having lost a drop of blood nor felt any pain.—*Paris Cor. Med. Press and Circular.*

Value of Combinig Heart Tonics.

Convallaria majalis is a simple cardiac tonic and safe remedy, in action similar to digitalis, but not so marked; it causes slowing and increases the force of the heart beats. But it will frequently be found in lessening compensation, that convallaria, strophanthus and digitalis individually fail or disappoint after a time; and that a combination of all three often produces an effect little short of marvelous. Once or twice in recent years I have been called in consultation over cases of advanced mitral disease, in which central failure has shown itself by extensive dropsy of the limbs, oedema of the lungs and liver, and a general water-logged condition of the system. On inquiry as to the exhibition of digitalis, the reply has been, "He has had it," with perhaps a like response as to strophanthus and convallaria. But they had not been given collectively; and when this was done, benefit speedily accrued to the patient, and credit to his medical advisers.—*The Clinical Journal.*

The Value of Mercury and Iodide of Potassium in Ophthalmic Syphilis.

M. Chibret, after 19 years of practice, believes that iodide of potassium has no specific value in the treatment of ophthalmic syphilis. 1. In ophthalmic syphilis, mercury alone always is effective; iodide of potash alone never is. 2. In general syphilis mercury alone acts almost always in all cases: iodide of potash alone on almost none. 3. In all cases of syphilis mercury alone is the touchstone to guide one in one's diagnosis. 4. Mercury, the specific for syphilis, is at the same time poison to the whole organism, and especially the nervous system. 5. Iodide in syphilis is often indicated to counteract the invidious effects of the mercury. 6. Iodide acts on lymphatic glands and rheumatism. 7. Severe syphilis is only affected by mercury or mercury in combination with iodide of potash. Iodide has not the local action that mercury has, but aids the patient to withstand the mercury treatment. The only thing to fear in the combined treatment is diarrhœa; when this appears stop treatment to continue it later in smaller doses. Iodine is only useful in those cases where a saturation of mercury is necessary. In other cases it is useless, even harmful for it diminishes the therapeutic action of the mercury.—*The North American Practitioner.*

SURGERY.

Torsion for Rectal Incontinence.

A recent paper of Dr. Gerster on this subject is interesting as furnishing additional information respecting the method reported by Gersuny, of Vienna, for the treatment of rectal incontinence described in detail in a previous report. The incontinence may be due to congenital absence of the sphincter ani, to paralysis of the sphincter from spinal lesions, or surgical injuries due to traumatism or operation. Gerster has used torsion with success to relieve incontinence. He rotates the free end of the gut around its own axis so as to arrange the folds of mucous membrane in spirals. The twisted gut is then sutured to the edges of the external wound. The amount of torsion is gauged by the amount of resistance felt by the index finger on introduction. He did not in two cases make more than one complete twist, but more than one revolution might be required when the freed end of the rectum was long, that is, when five to six inches had been excised and the end drawn down. If not twisted at once, the operation of torsion must be delayed till the rectum is fixed in a mass of granulations to the surrounding soft parts. It is then dissected clear for two or three inches, and twisted till the necessary resistance is obtained. Which method is preferable is not yet known. Gerster has never performed torsion immediately after extirpation, only after dissecting out the rectum, the proximal end when the dissection ended being fixed firmly when torsion was made.—*Boston Medical and Surgical Journal.*

"When in Doubt Operate."

The silly and ignorant crusade against what people are pleased to call vivisection seems to be joining handle with an even more silly and ignorant attack on life-saving surgery. To show the depths to which it is possible to descend, the old aphorism, "when in doubt, operate" has been twisted from its meaning, and paraded before the public as an illustration of the awful hankering after operation which is supposed to permeate and degrade the surgical mind. It would be difficult to imagine a greater perversion of truth than is conveyed in the suggestion that, in such a case of doubt as is there meant, the operation would be undertaken for the surgeon's instruction rather than for the patient's good. In case of hernia there can be no more life-saving rule than this of operating, if there is any doubt as to whether it may not be strangulated It was an aphorism derived from experience long before operations had the safety now given them by antiseptics; how much more should it hold true now. To give the patient "the benefit of the doubt" means to give him the benefit of the operation, and none but those who know nothing of the subject could have founded on the phase an argument against the tendencies of modern surgery.—*Brit. Med. Jour.*

Nitrate of Silver in Acute Inflammation.

Dr. Carrick in *The American Practitioner and News* draws the following conclusions:

1. That nitrate of silver is not as dangerous in acute urethral inflammation as is generally supposed.
2. That by beginning with small doses and increasing daily a tolerance can be established (the same as in chronic cases).
3. That when the discharge becomes very slight, it is better at times to decrease the strength of the nitrate of silver than to increase it.
4. That in cases of gonorrhœal cystitis, which are usually acute, good results are obtained by instillation of this drug.
5. That in cases of chronic, deep urethral inflammation, especially those of a granular nature, deep urethral injections are the remedy.
6. Nitrate of silver, as an abortive, should not be used, as in doing this peri-urethral inflammation may be set up, which might cause considerable harm.

Dr. W. Ross Martin reports a number of cases illustrating the value of Catterell's method in sprained ankle, which has the indorsement of Prof. Gibney. It consists in cutting strips of adhesive plaster about one-half inch in width and long enough to completely encircle the foot. Then with the foot still raised, it is strapped, ankle and lower leg included as you would an ulcer; the first strip passing over the outer side of the foot, down near the base of the little toe. It is placed obliquely, so that the next strip shall cross this; one end beginning under the heel and terminating under the ball of the great oe. The third overlaps the first about one-half, and is snugly applied, while the fourth overlaps the second in the same direction, aud so on until the foot is completely covered, including ankle and lower third of leg. It is, when finished, practically a Scultetus bandage. Over this a bandage of cheese cloth is applied and the patient allowed to walk about.—*Omaha Clinic.*

A Case of Laryngectomy by a Novel Method.

Dr. H. L. Swain reports the case of a laryngeal epithelioma removed by a new method. A sponge Trendelenburg canula was introduced into the trachea. The skin was incised from the sternum to the hyoid bone with a cross cut to the sterno-cleido mastoid. The larynx was carefully laid bare and bleeding checked. When all was cleared away, a director was carefully passed back of the trachea, between it and the esophagus, and the larynx severed from the trachea. The larynx was carefully dissected away from the anterior wall of the esophagus, from below, upward. When the arytenoid cartilages were reached, the direction of the incision was changed and directed toward the base of the epiglottis, including in its path the mucous membrane covering the aryte-

noids and portions of the ary-epiglottic folds. The epiglottis was cut through the tuberculm, and the larynx soon freed from all attachments. The epiglottis was then stitched to the posterior border of the opening, which had been the rima glottidis, and closed the ring completely, thus bringing the epiglottis in contact with the arytenoid mucous membrane, converting the ring into a linear wound running from side to side. The wound was united by continuous catgut sutures. A few strong sutures were introduced into the upper end of the trachea to prevent its slipping down. The result of this operation gave the following advantages over the older methods of operating: 1. The danger to life from inspiration pneumonia was very much less, owing to shutting off the mouth. 2. The patient can swallow as freely as usual. 3. The most wonderful of all, in at least three of the cases, similarly operated, a useful voice, fully as satisfactory as with an artificial larynx, was obtained and without the trouble that this latter entails. The possibility of recurrence by the irritation of the foreign body—the artificial larynx—could also be avoided. 4. There is less disfigurement than when wearing an artificial appliance. The author followed this method from seeing a patient that was presented by J. Solis-Cohen, who was able to talk easily and audibly with no communication from the pharynx and trachea.—*New York Medical Journal.*

Specific for Gonorrhœa.

A new specific for Gonorrhea is a one per cent. solution of creosote in decoction of hamamelis combined with boric acid. It is claimed that this will destroy the gonococci in two hours.—*Pacific Med. journal.*

When to Operate in Appendicitis.

Dr. D. A. K. Steele, of Chicago, in the *North American Practitioner* says:

My conclusions in regard to the indications for operation in appendicitis may be summarized as follows:

1. In cases where there is persistent pain, tenderness, temperature, increasing pulse, increasing tumor and progression of the disease.
2. In all cases where pus is present.
3. In all cases where salines and flushing of the colon does not give prompt relief.
4. In recurrent or relapsing cases in the interval following an attack.
5. Whenever the appendix is found diseased.
6. Whenever the appendix is found diseased during a laparotomy for any other condition it should be removed at the same time.
7. Operate immediately in all perforative cases.
8. Operate in all gangrenous cases.
9. Operate early and thus lower the mortality which is less than eight per cent. during the first week and over seventeen per cent. during the second week in cases operated.

2920 Indiana avenue, Chicago.

Appendicitis.

Dr. Dudley P. Allen, in a paper read before the Ohio Medical Association at Zanesville, wherein he reports thirty operations for appendicitis during the year with one death, submits the following conclusions:

1. Though many cases of appendicitis may recover without surgical aid, it is by no means an easy matter to distinguish these from those which are more serious, and it is of vital importance if surgical counsel is to be summoned it should be called before the disease is so far advanced as to render the operation hopeless.
2. Operations for appendicitis, though often easy, are at times extremely difficult, requiring the skill necessary for the most critical laparotomy, and I think it but right to say that it would be better in many cases to trust to nature than a poor operator.
3. Careful examination will disclose the fact that many patients suffering from what is supposed to be a primary attack of appendicitis have had previous difficulty in this region; and examination of the appendices removed will demonstrate positively the existence of long standing inflammation.
4. Operations in the acute stage of a primary attack are beset with danger, and it is important they should be undertaken before the patient is in collapse, before peritonitis has become general and before the patient is thoroughly septic.—*Railway Surgeon.*

The Prolonged Bath.

Modern Medicine says that a patient in the St. Louis Hospital was recently kept immersed in a bath tub for six weeks, for the cure of a large sloughing abscess, a current of water being constantly passed through the tub. The writer has, within the last twenty years, treated many cases of gangrene, crushed limbs, slouging sores, etc., by this method, and has found better results than by any other. Its success is due to the asepsis secured by the constant immersion. The presence of a large quantity of water is not favorable to the development of pus-forming germs, so that suppuration is lessened, and at the same time the poisons resulting from the action of the disease germs are washed away. These poisons, when left in contact with the tissues, paralyze the living cells and destroy them, thus hindering the reparative efforts; but by the constant cleansing effected by contact of water kept pure by frequent renewal, the tissues are protected from the toxic influence of these poisons, and healthful repair is thus promoted.

While in Vienna some twelve years ago, the writer found patients living in tubs of water, who had been immersed for periods varying from six months to a year or more. The cells of the body are accustomed to con-

tact with moisture; in this respect they may even be compared to aquatic animals. The blood cells are carried by a current of watery fluid, and the tissue cells are all constantly bathed in this fluid, so that the contact of water with the living tissues is a condition closely analogous to that which is naturally maintained within the body.—*Food.*

Treatment of Inoperable Malignant Tumors.

Dr. W. B. Coley, New York, in a paper read before the recent meeting of the American Surgical Association, in Washington, D. C., reported twenty-five cases of sarcoma treated by inoculating the patient with the toxines of erysipelas and bacillus prodigiosus, with six cures. Nine markedly improved and eight slightly improved. Also eight cancer cases, all but one of which showed improvement. The author's conclusions were as follows:

First.—The curative action of erysipelas upon malignant tumors is an established fact.

Second.—This action is much more powerful on sarcoma than carcinoma.

Third.—This action is chiefly due to the soluble toxines of the erysipelas streptococcus, which toxines may be isolated and used with safety and accuracy.

Fourth.—This action is greatly increased by the addition of the toxines of bacillus prodigiosus.

Fifth.—The toxines, to be of value, must come from very virulent cultures and must be freshly prepared.

Sixth.—The results obtained from the use of these toxines, without danger, are so nearly, if not quite, equal to those obtained from an attack of erysipelas, that inoculation should rarely be resorted to.—*International Journal of Surgery.*

GYNECOLOGY.

Picrotoxin in Gynæcology.

Dr. F. W. Talley states ("Philadelphia Polyclinic") that certain nervous symptoms are embarrassing to practitioner and prostrating to the patient; they are found in young girls suffering with ovarian disease, but mose frequently in middle-aged women who are approaching the menopause. At this time they increase in severity and continue from two to six years, with varying intensity. The symptoms are: Flashes of heat, cold creeps, sweats, cold hands and feet, flatulence, constipation, palpitation of the heart, melancholia. The patients are easily confused, their memory is impaired, they have crying spells, avoid crowds and public places, are suspicious and brooding, flushing when addressed, have a sense of impending calamity, and are generally wretched. For the relief of these symptoms strychnine, iron, arsenic, sumbul, asafœtida, valerian, and potash bromide have been exhibited. These, with rest treatment, attention to the bowels and to hygienic surroundings, often relieve the condition. There are cases, however, especially during the menopause, in which the relief from these drugs is only slight. For these cases Dr. Talley has used picrotoxin in 1-60 grain dose, repeated three times a day with the happiest results.

Calomel Plaster in Congenital Syphilis.

In the following preparation the sodium chloride and alkaline salts of the sweat transform the insoluble subchloride to the soluble perchloride, which is absorbed and keeps up a continuous action:

Calomel	10 parts
Castor oil	3 parts
Diachylon plaster	30 parts

Four square inches of this plaster ought to contain about 18 grains of calomel. A piece about 6 inches long and 4 broad is applied, after thoroughly cleansing the skin, and is renewed weekly.—*Brit. Med. Jour.*

"Chelsea Pensioner."

Lord Anson paid three hundred pounds for the privilege of publishing the following prescription for chronic rheumatic arthritis:

Sulphur	℥ i.
Cream of tartar	℥ i.
Rhubarb	℥ iv.
Gum guiac	℥ i.
Make 1 powder and add honey	℥ xvi.

Mix well, and take 2 tablespoonfuls in a tumbler of white wine and hot water on going to bed, and repeating the dose on getting up in the morning.—*Louisville Medical Monthly.*

OBSTETRICS.

Uncontrollable Vomiting of Pregnancy.

Bonnet (*British Med. Jour.*) relates a case where the patient was 22, and single. Her first pregnancy went on to term; but, in her second, labor was induced at the fourth month in consequence of hyperemesis. During the early part of the third pregancy vomiting became very severe, lasting a month, and reducing her to an alarming extent. When just over six weeks pregnant, a laminaria tent was introduced; on January 14, 1890, the vagina was plugged with iodoform gauze. For twenty-four hours the vomiting ceased. Next day the tent was removed, and the sickness returned. On January 17, two tents were introduced as high as possible. The vomiting again stopped, returning when the tents were taken out. Then five tents were progressively introduced, and left in place for three days. The sickness stopped, and did not return. The uterus showed no signs of contracting throughout the course of the above treatment. The patient took food well and grew stout. Seven and a half months later she was delivered of a healthy child at term.

Hemorrhage in Pregnancy.

Cases (N. Y. *Med. Times*) are by no means rare where slight hemorrhage, or something resembling menstrual flux, occurs at the time for the regular catamenial period for the first two months of pregnancy, and in some cases extends during the entire period. This condition does not necessarily indicate placenta prævia, for where that exists Prayfair says that hemorrhage rarely begins before the end of the sixth month, and sometimes not until labor has commenced. Depaul, in seventy cases, says in one case only the hemorrhage occurred before the sixth month; in seven from six to seven months; in twelve from seven to eight months; in twenty-six from eight to nine months; and in twenty-four at term or near. A month before actual labor is not unusual for slight pains, resembling labor pains, to occur at regular intervals, even with the slight appearance of blood. Of course, in these cases the strictest rest should be enjoined, and, if necessary, some remedy used to check the pain.

The belief is as old as Hippocrates that hysteria is cured by marriage. But Dr. Wythe Cook finds, from his experience, that in most cases of dysmenorrhœa and hysteria among single women marriage aggravates the disease. Hysteria is by no means cured by marriage, dysmenorrhœa often returns after pregnancy.—*Amer. Jour. Obstetrics.*

Can Ovarian Dermoids be Diagnosed?

Guinard (*British Medical Journal*) denies that there is any one pathognomonic symptom of dermoid cyst of the ovary. Three signs, on the other hand, when they occur in the same patient, almost assuredly indicate this disease. These signs are pain, slow growth, and consequent small bulk of the tumor, and relative youth of the patient. Tillaux and himself have both found that these signs are reliable. Exploratory puncture is absolutely unjustifiable. Should the tumor be dermoid, puncture is especially dangerous, as the contents of a dermoid cyst are highly irrigating to the peritoneum. Guinard admits that there is one source of fallacy in his test for dermoid of the ovary. The pain may be due to torsion of the pedicle of an ordinary ovarian cyst, and as torsion checks the growth of the tumor and may occur in a young subject, diagnosis in the simplest-looking case must be reserved.

Incontinence of Urine.

Dr. White, *La Revue Medicale*, recommends the following formula in incontinence of urine in children:

Benzoate soda	āā grs xv
Salicyate soda	
Ext. belladonna	grs xxx
Cinnamon water	ʒ iv

A teaspoonful four or five times a day.

—*Canada Lancet.*

DISEASES OF THE EYE.

The Removal of Foreign Bodies from the Cornea.

Mechanics and workmen have learned from oculists (who should have taught them better) the method of removing foreign bodies from the cornea by "picking them out" with some sharp or slightly blunted metal instrument. In every factory or workshop every day, and often many times a day, it occurs that pins, knives, etc., are thus blunderingly used, frequently with great injury to the cornea, with the resultant formation of corneal ulcers, keratitis, iritis, or at least, leucomata. All text-books of ophthalmology advise the use of the "corneal spud" for removing such particles, and every young physician supplies himself with the instrument. But it is the most outrageously ill-adapted for the purpose conceivable. It is impossible for any patient to hold the eye still enough to permit any hand thus to remove a partly-imbedded grain of sand, or emery, or what-not, without wounding the epithelium of the cornea. For this purpose a rigid tool is absurd, and a rigid metal instrument is the acme of absurdity. Every physician should teach workingmen how easy it is, and how free from any danger of injury, to remove the great majority of foreign bodies on the cornea with a simple wisp of cotton. Any particle not thus removable should not be sought after with pen-knives, awls, pins, or spuds, but the patient should be sent to a physician. Twist a little wisp of absorbent cotton, having long fibres, upon itself until the fibrils are well caught, but are not too densely packed, upon each other. Fold the roll upon itself and grasp it half an inch from the rounded or curved extremity. The eyelids are held apart by the fingers of the left hand, and the patient instructed to look in such a direction as to bring the foreign body into view. By delicate, though firm pressure, the wisp of cotton is brushed, not too quickly, across the cornea, or it is given a slight twist or screw-like movement when deftly pressed against the cornea. Almost invariably the dust-particle is removed at the first trial, being entangled or caught by fibrils of the cotton. Cocaine, blepharostat, spud, time, labor and injury are all dispensed with and happily spared. The procedure may not be for the commercial advantage of the specialist, but it is worth more to the world than seven "original researches" and prize essays.—*Medical News.*

The Treatment of Ophthalmia Neonatorum.

Kalt recommends irrigation of the eye with a 1 to 5000 solution of potassium permanganate introduced through a small funnel, one end of which is placed between the eyelids and the other connected with the bottle containing the fluid, which should be placed about a foot above the patient's head. The irrigations should be made twice a day, and two quarts of the fluid should be used at each

time. If the disease is attended with serious or extensive trophic changes in the cornea, the irrigations must be used more frequently —say four times a day—and gradually lessened as the inflammation disappears. (At a recent meeting of the Ophthalmological Section of the New York Academy of Medicine, this plan of treatment was favorably commented on by Dr. H. Knapp, who had seen its application by Kalt.)—*Med. Record.*

SKIN DISEASES.

Behrend (*Berlin*) considers that the difficulty in curing pityrasis versicolor is due in many instances to the popular impression that the disease is confined to the covered portions of the body, and that the disease on the exposed parts is a constant source of reinfection. Permanent lasting recovery, says Dr. Behrend, can only be realized by three agents, as far as is known, viz.: (1) tincture of iodine; (2) chrysarobin; pyrogallic acid. Tincture of iodine is objectionaole on account of its liability to cause permanent pigmentation.

Pyrogallic acid is less effective than chrysarobin, and the author therefore gives preference to the latter. (*Ned. Wick.*, Vol, ii, No. 44.)

All of this is very well, but to my mind chrysarobin and its stain, and likelihood to systemic intoxication is as objectionable as either the tincture of iodine or the pyrogallic acid. The author has completely ignored the factor clinically and fully demonstrated by Neilssen, of Copenhagen, last year. Nielssen demonstrated that the reinfection of pityriasis versicolor, apparently at regular intervals and seasons was strikingly coincident with the time at which the underclothing was changed, viz.: in the spring and fall. He elucidated from a number of cases that before the appearance of the eruption the patient had either worn newly bought underclothes, not having been previously washed, or else the underclothes worn had lain in a clothes press for a season. The fungus of micosporon furfur was found by him on such underclothing, dampness and absence of light favoring the development of the micro-organism. Simple parasiticides will destroy patches of pityriasis versicolor, and that in a short time. After reading Nielssen's article I began observations upon this class of cases and had the satisfaction of confirming his clincial evidence regarding the underclothes theory.—*Dyer in Texas Med. Jour.*

DISEASES OF THE NOSE.

Teach the Children to Clean Their Nose.

One not in the daily treatment of diseases of the nose would be surprised to know how many children are daily met in a large practice who cannot clean their nose; who have never been taught how to blow their nose. The neglect of such neglected teaching is bad, always filthy and frequently dangerous. I have seen children eight and ten years old who could not blow their nose and who had ever present in their nasal cavities large accumulations of nasty mucous. Such children are, of course, of the lowest class and cannot be expected to know the laws of health or how to observe it. In this matter the teachers in our public schools should take such cases in hand. Pent up secretions in the nose do much injury to the child.—*Briggs in Texas Health Jour.*

Profuse Hemorrhage from Removal of Nasal Polypus.

The surgeon who operates daily soon comes to look upon "alarming hemorrhage" as found in the books only. I seldom think of hemorrhage at all and more especially from so small an operation as removal of nasal polypi. On the removal of a very large nasal polypus recently I was, however, convinced that the most alarming hemorrhage may follow. The girl was thirteen years of age and apparently healthy. The polypus weighed over an ounce and while protruding from the nose also hung down in the pharynx. It was seared and cut away rapidly in hard chunks until the pedicle was reached and when it was cut there was an arterial spurl which was most profuse and hard to check. The pedicle had its attachment in the ethmoid bone. Finally a clot was formed and the child made a rapid recovery. In all such cases always be prepared for posterior plugging.—*Texas Health Jour.*

NEWS AND MISCELLANY.

The Baltimore Meetings of the American Academy of Medicine.

PRELIMINARY PROGRAM.

The twentieth Annual Meeting of the American Academy of Medicine will be held in one of the buildings of the Johns Hopkins University, Baltimore, on Saturday, May 4th, and on Monday, May 6th, 1895. The "Headquarters" of the Fellows of the Academy and the meetings of the Council will be at the "Stafford."

The meeting will open at ten o'clock on Saturday morning with an executive session of the Fellows of the Academy exclusively; the reading of the papers will begin at about eleven. The morning session will close at one o'clock, and the session of Saturday afternoon will extend from three to six. The "Reunion Session" will be held on Saturday evening. By a standing rule the price of the tickets for the supper is fixed at two dollars. Attendance at the reunion session is not con-

fined to the fellows exclusively, hence any member may bring friends with him by arranging for their tickets with the committee. For the past two years ladies have been present at this session and have added to the enjoyment. The session of Monday will begin with a short executive meeting, after which the reading of papers will be resumed; after a recess at one, the afternoon session will begin at three and continue until adjournment.

Members of the profession, and others who may be interested in the topics treated by the papers, are cordially invited to attend the open sessions of the Academy.

The following are the titles of the papers that have been promised:

1. The address of the retiring president, J. McFadden Gaston, Atlanta, Ga.
2. "Expert Testimony," Henry Leffmann, Philadelphia.
3. "Hospital Management," W. L. Estes, South Bethlehem, Pa.
4. "The Proper Teaching of Physiology in the Public Schools as a Means of Preventing Intemperance and Venereal Disease," De Lancey Rochester, Buffalo, N. Y.
5. "The Problem of Dependency as Influenced by the Chinese in America," W. F. Southard, San Francisco.
6. "What Agencies Conspire to Check Development in the Minds of Children," J. Madison Taylor, Philadelphia.
7. "How to Avoid the Dispensary Abuse?" Emma B. Culbertson, Boston.
8. "Contract Medical Work and Fees," Charles P. Knapp, Wyoming, Pa.
9. "What shall we do with our Alcoholic Inebriate?" J. W. Grosvenor, Buffalo, N. Y.
10. "Life Insurance in its Relation to one of the Dependent Classes," E. O. Bardwell, Emporium, Pa.
11. "Some Results of Competive Medical Charity," George M. Gould, Philadelphia, Pa.
12. "Criminal Anthropology," E. V. Stoddard, Rochester, N. Y.
13. Title to be announced, Leartus Connor, Detroit, Mich.
14. "The Increase in Insanity," Gershon H. Hill, Independence, Ia.
15. "A Perfect Consultation," L. Duncan Bulkley, New York.
16. "An Analysis of the Reports of the Examinations by the State Boards of Medical Examiners," Perry H. Millard, St. Paul, Minn.
17. "The Limits of a Physician's Duty to the Dependent Classes," James W. Walk, Philadelphia.
18. "The Economic Aspect of American Charities," Bayard Holmes, Chicago.
19. "Is our Financial Relation to our Patients and Community the best Possible," Woods Hutchinson, Des Moines, Iowa.

Partial promises have been made for several additional papers; it is hoped that these can be definitely mentioned when the completed program is issued.

Members preparing papers are urged to send a copy of the paper, or an abstract, to the Secretary as soon as possible, in order that time may be given him to prepare the press reports. If others than those mentioned contemplate the preparation of papers, information should at once be sent to the Secretary, as the completed program must be issued early in April.

Annual Meeting of the American Medical Association at Baltimore, Md., May 7, 1895.

The Section on Neurology and Medical Jurisprudence have arranged the following symposiums for the May meeting at Baltimore:

Epilepsy: Medically, surgically and therapeutically.

Hypnotism and mental therapeutics, and its medico legal relations.

Electricity: Some new therapeutical relations and questions of treatment.

Short practical papers on these topics are urgently solicited. Other papers on subjects belonging to this Section will be welcomed. Address

T. D. CROTHERS, M.D., *Secretary*,
Hartford, Conn.

The Obstetrical Society of Cincinnati at its annual meeting elected the following officers for the ensuing year:

President, Dr. A. W. Johnstone; Vice President, Dr. Sigmar Stark; Secretary, E. S. McKee; Corresponding Secretary, Dr. W. D. Porter; Treasurer, Dr. Geo. E. Jones.

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING FEBRUARY 15, 1895.

George Purviance, surgeon; detailed as chairman board for examination of assistant surgeons for promotion, to convene in Washington, D. C., March 11, 1895, February 8, 1895.

J. B. Hamilton, surgeon; granted leave of absence six days, February, 1895.

H. W. Austin, surgeon; detailed as member board for examination of assistant surgeons for promotion, February 8, 1895.

Fairfax Iruvin, surgeon; detailed as recorder board for examination of assistant surgeons for promotion, February 8, 1895.

W. G. Stimpson, past assistant surgeon; to assume temporary command of service at Port Townsend, Washington, during absence of Past Assistant Surgeon J. O. Cobb, February 13, 1895.

J. M. Eager, assistant surgeon; ordered to examination for promotion, February 9, 1895.

Rupert Blue, assistant surgeon; granted leave of absence for six days, February 18, 1895.

Seaton Norman, assistant surgeon; ordered to examination for promotion, February 9, 1895.

CONSUMPTION; ITS PREVENTION AND TREATMENT.*

T. F. WOOD, M.D., ANGOLA, INDIANA.

The old and trite saying that a nation's strength is a nation's wealth, is self-evident; that both are largely dependent upon its health, is a fact which is readily recognized by all who have given the subject proper thought. The preservation of health should, therefore, be the first duty of the physician to mankind. His second, that of restoring health when impaired. That old, common and ruthless destroyer of human life, consumption, may well engage our earnest attention. We will probably not be able to demonstrate any new theories, but propose only to speak of some of the more common, simple and avoidable conditions which ultimately lead to the development of tuberculosis.

More than a century ago, consumption was treated by some nations as a contagious disease. Tuberculous subjects were isolated with a view of preventing the spread of the disease by contagion or infection. Physicians were required to report all cases of the disease, and those afflicted were registered by the proper authorities as consumptives. All clothing, furniture, etc., used by them was either thoroughly renovated or destroyed. After death, the rooms occupied by them were rigidly disinfected. These regulations were enforced for a period of more than fifty years, with the result only of showing the futility of such measures. They will continue to be fruitless unless they are founded on a correct understanding of the way in which the contagious material is transmitted from one individual to another, the conditions most favorable for its reception and the liability to produce its characteristic results after finding lodgment in the system.

While the contagious nature of consumption was admitted at an early day, positive proof of its communicability was not furnished the profession until the researches of the immortal Koch were published in 1882, since which time, other bacteriological investigators have sustained his views by their investigations in this branch of medical science. The result and final conclusion of these experiments and investigations is that the exciting cause of tuberculosis is the tubercle bacillus. A logical sequence of this conclusion would naturally be that the disease is communicable and, consequently, preventable.

In the face of all the facts connected with the contagious character of the disease, the impression still exists to some extent that it is a matter merely of opinion; that equally competent and reliable authority is arrayed on either side

*Read before the Northern Tri-State Medical Association, December 11, 1894.

of the question. With the laity and that part of the profession not given to investigation and who are skeptical as to the correctness of the conclusions of many of our more brilliant bacteriologists, the question will perhaps remain unsettled. While our facilities for the study of this branch of medical science are quite limited, we are disposed to give due credit to the teachings of those who are in position to be authorities upon this subject.

A knowledge of the more common causes of consumption is necessary for an intelligent and profitable study of its prevention and treatment. The facts connected with its causation and manner of transmission, I think are fully established, and are based upon careful experimental observations. There is little room for doubt or for difference of opinion regarding the main factors in its causation. Really none among those conversant with the scientific conclusions reached by the improved methods of the modern bacteriological student. To dwell on this particular line may seem superfluous, but we wish to be plainly understood as being a disciple of the teaching that there are only two principal conditions necessary for the development of the disease. This being true, all our efforts in the direction of prevention or treatment, should be to so change or modify these conditions that the ultimate result may be reduced to the minimum.

The two factors necessary to the development of tuberculosis, are the tubercle bacillus and the predisposition or condition of system favorable for the development of the disease after the reception of the germ. In all infectious diseases, there are two forces at work: *First*, the number and virulence of the germs that may gain admission to the body at any given time. *Second*, the resisting power of the system or its ability to successfully combat the poisonous influence of the infectious material and thereby render negative its results as regards the development of disease. The resisting power depends upon several factors, prominent among them being the avenue by which the germs enter the body, the vital condition of the tissues with which they come in contact, and the general nutrition of body at the time of exposure.

A large per cent. of people who are exposed to contagious diseases, are not attacked by them. Especially is this true of consumption. The explanation lies in the fact that the natural power of resistance to the tuberculous germs is so great at time of exposure that the disease is not contracted. The facility and certainty with which it is transmitted is minimum compared with many other diseases. Usually, protracted exposure to the infection, or intimate relation with those afflicted with the disease, is requisite; or, perhaps, the resisting power is such that it is easily overcome. Any influence of a depressing nature renders the system more susceptible, and hence the transmission of the disease more certain.

Of the two principal avenues by which the germs enter the body, the respiratory passages is far the more common; hence, anything that weakens the vitality of these parts renders individuals much more susceptible to the infecting influence of the germs. Unhealthy occupations, defective ventilation, imperfect nutrition, whether from improper food or from insufficient quantity, heredity, bronchial or pulmonary inflammations, and many other things might be mentioned as important factors in creating a soil favorable for the growth and development of the bacilli after reception into the system. These factors act as predisposing causes by rendering the resisting power less efficient in the fight for the ascendency between the cells and the germs. Yet, they only provide the predisposition; the fact, as taught by bacteriology, remains that no one, nor all of them combined, can produce the disease independent of the tubercle bacillus, which is the chief or exciting cause and without which tuberculosis is never developed.

The respiratory tract being the chief avenue through which the infectious material is received, and the germs being so universally present in the air, the inquiry will naturally arise, Why is it that so few become diseased, as compared with the great number who are exposed to the invasion of the bacillus by inhalation of atmospheric dust? Evidently the reason for this is the fact that a great majority of the people exposed, have an amount of resisting power sufficient to avoid infection by the tuberculous germ. The anatomical arrangement of the respiratory organs and the peculiar characters of the mucous membrane lining the bronchial

tubes, are such that all dust is lodged upon its surface and much of it is subsequently thrown off in expectoration. Tubercle bacilli are taken up in the same way and, often times, disposed of in a similar manner; or they may be retained until their vitality is destroyed and they become incapable of infecting the tissues in their characteristic way. In these cases there is a conflict between cell and bacillus. If, now, the mucous surfaces are healthy, the lungs in good working order, the cells entering into their formation vigorous and the general environment of the body not weakened, good health will be maintained. If the contrary, tuberculosis is more than likely to be developed. Inability to resist the special work of the tubercle constitutes a predisposition to the disease, and is much stronger in some persons than in others; but it is probably developed by a train of circumstances, similar in most cases.

In considering preventive measures, it is essential to look after some of the causes that lead up to the establishment of this predisposing condition. We make only general suggestions to the effect that it may be inherited, or acquired, or both. Children of consumptive parents do not inherit consumption, and many of them never have it; but they are more liable to be weak and unable to resist the influence of the disease-producing germ. This is not only true of the progeny of consumptives but those born of parents suffering from any malignant disease are quite liable to be deficient in physical ability.

Among the many causes leading to the acquirement of the predisposition, only a few need be mentioned: breathing impure air; the use of unwholesome food; the existence of other lung and bronchial diseases; want of proper exercise; abuse of the use of alcoholic liquors; disease of the kidneys—in fact, anything which leads to a deterioration of the general health, or a weakening of the tissues upon which the bacilli find lodgment. These various factors seldom act singly in the causation of consumption, but in the study of individual cases, we see the influence of many trifling circumstances, the combined force of which seems to act in one line, producing the disease.

In discussing measures to be taken for the prevention of consumption, a thorough conception of its communicability, curability and prevention should be had; and these propositions should be taught the laity, as well as the profession. The people should understand that, from a sanitary and economic standpoint, all other diseases sink into comparative insignificance.

It is usually so insidious and slow in its progress that its gravity is not realized; its ravages are so common that we become accustomed to them and are indifferent about adopting common, simple and easily applied measures for its prevention. Perhaps this indifference is due to the fact that much time often elapses after exposure to the exciting cause, before the disease is manifest; or it may not be developed at all. Again, we quite often hear the remark that the early symptoms are only "a cold," a bronchitis, etc., until such inroads are made that the adoption of any measures looking to prevention or treatment, avails but little. Consequently the laity regard consumption as meaning death, notwithstanding all the wisdom of modern medical science. The proposition is nevertheless true, that the disease is curable, and curable in quite a large proportion of cases if its nature is well understood; if it be recognized early and appropriate measures are employed to prevent its extension.

We urge the importance of more thorough education along this line; and expecially upon the two main points, namely, to correct the predisposition and prevent the reception of the tubercle bacillus into the system. These two things accomplished, its mortality record will be much reduced. While we may in this brief article, make only some general suggestions in this direction, we firmly believe that with our present knowledge and the methods at our command for studying the causation, dissemination, etc., of the disease, the time is not far distant when we will be able to formulate and adopt measures which will almost certainly prevent its occurrence. Of all the contagious diseases consumption is certainly one of the easiest to prevent, as it is one of the most unsatisfactory to treat after it is well established.

The first step looking to the study of preventive medicine, especially regarding tuberculosis, is to educate the people and

make them realize that a chief object of medical science is to prevent disease, as well as to treat it; also, that their coöpertion with the profession is essential if they would realize all that is possible in this direction. It should be the duty of sanitary authorities, both State and municipal, to employ comprehensive and efficient means for the prevention of tuberculosis. Need I say that these measures should be thoroughly studied and taught in a general way, by every practitioner of medicine? We should instruct the people relative to the communicable nature of the disease; instruct them as to the plans to be adopted to render the sputum innocuous; teach them how to prevent its being taken into the air as dust particles; inform them of the best method of caring for wearing apparel, disinfection of all clothing, etc.; in rooms occupied by the victims, the cleaning of walls, floors, furniture, etc. In short we should educate them as to a thorough renovation of everything that has been used in caring for a consumptive. We should recommend the establishment by law, of such measures as shall prohibit the employment of tubercular persons in factories, school-rooms and such other situations as will expose the health and endanger the lives of other people. We should urge the importance of sanitary regulations along the line of prevention of tuberculous dissemination in public gatherings, especially in halls, churches, school-houses, etc. We should teach that success in treatment depends materially upon an early diagnosis; consequently that a microscopical examination of the sputum in suspected cases will make our treatment more efficient.

In view of the transmission of disease by and through food products, certain regulations should be adopted by the government whereby dairy cattle should be inspected, together with those to be slaughtered for food. Slaughter houses, with their environments, should be under governmental supervision, as regards purity of meats; and all meat not thus inspected should be barred from sale, both public and private.

The establishment of hospitals by the public for the treatment of the consumptive poor, should be recommended in all localities where expedient.

The influence of our knowledge should not only extend to the community in which we live but to corporations which have under control the means of public travel, whose business it is to furnish conveyance from point to point through our country. We disapprove of the promiscuous occupancy of conveyances by well and sick alike, regardless of the nature of the ailments of the latter. We refer particularly to the sleeping apartments of steamships and railroad cars.

Regarding the merits of the measures suggested, opinions will justly differ both as regards the plans and the feasibility of their adoption. At this particular epoch in sanitary science, it is our opinion that some decisive steps should be taken in this direction. While we might not be able to establish any arbitrary rules, there would be germinating points, from the growth of which great good would ultimately come. In this way, our country would be made stronger; and as well suffering thousands relieved from disease and premature death.

We come now to the treatment proper, of which we shall speak in a general way only, making suggestions relative to the employment of drugs, diet, hygienic and climatic treatment, which we think may prove beneficial in a majority of cases as they present themselves for treatment. The management of each case should be a separate study, proper attention to which will suggest appropriate remedies. Reviewing the treatment, we find changes as radical, the benefits derived therefrom as great as are the improved methods of diagnosis. Depletion, stimulation and starvation in various ways entered into the history of the treatment of disease in the past, and tuberculous disease has been no exception to the rule. We find these methods have been strenuously followed, and we believe many times with disastrous results to those receiving it. This unscientific way of treatment has, perhaps, been largely responsible for the great mortality attending it, and for the lack of confidence regarding its curability which has prevailed among the laity. When the profession began to make a more searching inquiry into the etiology, treatment became more rational, with a gradual decrease in the percentage of mortality. The number of remedies employed has decreased, while the efficiency of those used is much more satisfactory.

In the general plan of treatment which

we would suggest, the environments or surroundings should first engage our attention. For the purpose of brevity, we will include under this head, the location and arrangement of apartments (if patients are confined indoors), the clothing, food, exercise—everything save drugs. Make the surroundings of every invalid such as to prevent all worry, anxiety, etc., so far as possible. If they must go down the declivity, help them go slowly. In short, our patients should have an abundant supply of pure, fresh air and sunlight; warm, clean clothing on a clean body; plenty of well prepared nutritious food, pure, rich milk, being superior to all others. Add to these such home influences as will make life worth living.

In the development of drugs, use only those whose therapeutic action would make them valuable in maintaining the normal physiological condition of the system in every particular. In this way, if any, we maintain a vigorous healthy action of every cell that is liable to attack by the tuberculous germ. If possible, maintain perfect digestion and assimilation, which secures good nutrition, for good nutrition to this class of persons means the perpetuation of good health and life—the opposite, disease and death. In our opinion, but few drugs are required to accomplish all that can be done in the way of medical treatment. Chief among these are iron in its various forms, quinine, strychnia, arsenic, creosote, iodide of potassium, the hypophosphites, cod liver oil, morphia, and a few others to meet special indications.

A judicious use of these remedies in appropriate cases, under the guidance of thorough and careful practitioners, we believe will cure many cases, prolong the life of others with comparative good health, and make the pathway to the grave of the incurable smooth, easy and without friction, so that their years of invalidism may be spent with as much comfort as is attainable by treatment.

THE EARLY DIAGNOSIS OF TYPHOID FEVER.*

PROFESSOR V. HANOT, PARIS.

Typhoid fever is one of those acute, infectious diseases which is most prone to an atypical course, which lasts longest, and for which responsibility weighs heavily on the physician on account of its attacking usually young persons, with their deep interests in life.

During all this morbid evolution, which is often so tortuous and deceiving, one will be under constant surveillance and be strictly judged. Therefore, have a care not to utter a word that may conflict with your ultimate diagnosis and never appear surprised; for the interest of the patient requires the physician to posses the full confidence of his friends.

It is true that the diagnosis is ordinarily easy and the treatment fixed by rule; but the disease may burst upon one at any time, and find him unprepared. On the contrary, if early appreciated the disease may often be kept within bounds and be led on to a favorable issue. Therefore study carefully each case of typhoid fever which you may meet and even if fortune forsake, you will be assured that you are worthy of the mission confided you.

How does typhoid fever begin? Here is the first stumbling block and not the least embarrassing of a medical career. The problem is often very difficult to solve. First of all, I would have you keep in mind that it is rare that typhoid fever begins suddenly with chills and fever, and that it is not a disease with a violent beginning as pneumonia, erysipelas or scarlatina, but that usually it developes in an obscure manner, and only little by little, after an undecisive course, does it assume a definite form.

When the pathogenic microbe has penetrated into the intestine it is not in the midst of an ideal culture medium as in the laboratory, but the field is already occupied by other germs which, to employ

* Translated from La Semaine Medicale, No. 63, 1894 by F. H. Pritchard, M.D.

Metchnikoff's expression, act either favorably or unfavorably upon its development. Decreased or increased in morbid power by this first conflict it invades the organism which reacts and resists in a different manner according to the age, social standing, constitutional predispositions, former hereditary weaknessess, etc. From these proceed the differing variations of typhoid fever. Generally typhoid infection of the organism, whatever may have been the initial condition, reveals itself at a given moment by a thermic evolution, with a definite cycle, in three stages which are quite distinct: first, a stage of ascending oscillations; second, a stage of stationary oscillations; and third, a stage of descending oscillations. This is called Wunderlich's temperature curve. But this tracing is not exactly parallel for, before the invasion of the organism, the disease undergoes a preparatory elaboration which is performed in absolute silence or with badly characterized signs. Therefore, it is convenient to admit in this period of incubation—in this propyretic stage as Gueneau de Mussy calls it—a first phase which is absolutely latent, and a prodromic period, properly called, which is marked by the first appearance of malaise and even by a slight and irregular febrile movement. I shall tell you later that it is exceptional that one is able to obtain a complete tracing according to Wunderlich and especially if one attempt to discover the first elevation from a complete state of apyrexia. These are the signs which should be first tracked out and of which the exact interpretation should be made. This prodromic period represents, on a small scale, a typhoid fever which is germinating and extending. You have been able to form an opinion from the eleven cases of typhoid which we observed during the last six months. Let us take as a type the young clerk who lies in the sixth bed of the Magendie ward.

Aged twenty years, he has only been living in Paris for eighteen months, and has always been in good health. At his entrance into the hospital he had been sick for about a week, he having been seized towards evening one day with a feeling of weakness and with pains in the muscles upon the least effort. The next morning he felt somewhat better, but soon his usual work became too much for him; his sight became dim, his mind confused and for a short time he fell into a half stupor, after which he returned to his work. It was not long before he commenced to complain of his head, roaring in the ears, dizziness and chilliness. He staggered in walking and he was forced to leave his work before the usual hour. He went to bed feeling sore, depressed, restless and slept but little or none at all. He was entirely without appetite, with a bad taste in his mouth and a pasty coating on his tongue. He had had at the beginning alternating constipation and slight diarrhœa, with some colic. The patient thus tried for six days to keep at his work, but on the seventh, finding it impossible he entered our service. We found his mind clear, and about in the condition of the preceeding days, which he described to us with precision. The rectal temperature, on the evening of his admission, was 37.6° C., the next morning 37.2° C., that evening 37.2°, the morning following that day 37.4° and that evening 37.8°. From this moment it increased progessively, to attain four days after 39.4° in the morning and 39.9° in the evening, at which figure it remained, with variations of some tenths of a degree for twelve days, when it began to descend and finally entered into the apyretic period, during all of which time the characteristic symptoms of the disease developed.

The prodromic stage had lasted eight days and had presented the appearance of a shortened attack. You will remark that he has had no epistaxis. Epistaxis is an expressive and habitual sign of the beginning, but it is neither constant nor pathognomic. It is also observed at the beginning of other infectious acute diseases and again it may frequently be lacking. Thus, out of the twelve last typhoid cases we have observed it but five times. The statements of the patients should be received with caution, for we cannot always confirm them by those of the family. Therefore, ordinarily, the prodromic period is not characterized by anything localized nor conclusive; hence, here is the first difficulty.

You are called, for example, to a young man or a young lady whose health has been insensibly disturbed as in the case I have just related you. The parents are anxious; the parents are always ready to think their children attacked by typhoid fever, for they know that at their age they

are particularly liable to be attacked by this disease which has still a feared name. Therefore, they are all anxious and press you. They call you aside and put you through the same list of questions. What is it? Is it not the typhoid fever? Now, it is most frequently at this period impossible to give a decided answer. At all events, do not pronounce the word typhoid fever until absolutely certain of the diagnosis. Do not become frightened too soon and especially without cause. The friends will not pardon you for such a cruel error.

Therefore, examine your patient very carefully and attentively; be prudent and reserved. The case is possibly that of a candidate for an examination for a concours; possibly, that of a workman who has been overworked or undergone privation, or that of a high liver who has given himself up to excesses. Think also of a gonorrhœa which might have been concealed. The patient is perhaps of a consumptive parentage and you are in the presence of one of those cases of tuberculosis with an insidnous beginning which bear the impress of typhoid fever. The case may be again that of a young girl who has been affected by a violent emotion. Is it hysteric fever? The patient is in the midst of an epidemic of grippe or typhus fever. Is it either of these? Remember that sometimes in tuberculosis the initial manifestations of syphilis are preceeded by a germinitive phase which is analogous to that of typhoid fever. You will call to mind each of the morbid states mentioned and remember how their respective beginnings differ from that of typhoid fever. Hold in mind, besides the time which the patient has been living in Paris or any other large city, the season, the coexistence or not of an epidemic of typhoid fever. Find out if he had the disease before, for recurrences are very rare, though possible.

In spite of all this it will be frequently more than once difficult for you to fix your diagnosis. Ordinarily, it must be admitted, the hesitation will not last long; the characteristic symptoms are not long in appearing, but often also the prologue will be very long and your indecision and embarrassment will increase. Therefore, you must know the possible duration of the prodromic period for it may be very variable. During the two years which I was interne at the Hospital Cochin under Bucquoy, which then had only one medical service, there appeared one day a young man who did not desire to enter the hospital, but only asked for relief. He complained of being without appetite and feeling weary. Nothing else was to be discovered and he was given a purgative and advised to rest. Several days after he reappeared feeling no better. His appetite and strength were still the same. No appreciable signs of fever could be discovered nor other typhoid signs. He again refused to enter the hospital. Several days later he again returned, but this time dragging himself along with difficulty, and accompanied by a comrade who had brought him in a carriage. His face, the state of his tongue and the fever could leave us no longer in doubt; it was typhoid fever.

As he had first been seen ten or fifteen days before, for the first time, one would think that he was least at the end of the first week of his disease, having had at the beginning a typhus levissimus or ambulatorius. Yet at the first examination in the ward we were able to find neither sibilant râles in his chest, nor the rose-colored "rash" upon his abdomen. His temperature did not go above 38°, and it continued to rise for two or three days, when the râles were observed and soon after the characteristic "rash."

The patient was therefore only at the second, third or fourth day of his disease and the preceding days of malaise represented the germinative or prodromic stage which is usually only four to six days. Now out of twenty cases where I have been able to note the prodromic period precisely, which was generally from four to six days, I have found seven where it lasted from fifteen to twenty days and further observation was able to prove that the ultimate course was not due to relapses but was marked by the grand characteristic lines and episodes of a typhoid attack. During these two years, where the conditions for observation were especially favorable, I have not been able to obtain a complete and tracing of Wunderlich's ideal temperature curve. Either the patients escaped observation during this period or they did not enter until the disease was well developed. Whatever it be that which I have stated is in accord with the statements of a large number of

writers. The prodromic period or that portion of the period of incubation which consists of the first malaise to the setting in of definite febrile symptoms lasts, according to Murchison, from one to several days; Griesinger puts it at two to five days as an average and sometimes even seven or to fifteen days and over; Guéneau de Mussy would fix it at two weeks, on an average, and sometimes even three weeks.

These variations should not astonish you for as I said before the pathogeny of infectious diseases is subordinate to a multitude of conditions. The organism may be more or less predisposed by former excesses or constitutional defects or the germ may be particularly virulent or associated with other pathogenic microbes. The microörganism does not present the whole morbidific power for the individual also plays his part. You perhaps are familiar with the fact reported some time ago by Quincke, of fourteen persons who had, at the same time, drunk of water contaminated by the dejections of typhoid patients and who were all seized with the disease in eight to ten days after, yet the mode of beginning differed notably.

Thus, in two or even three weeks, it may be impossible for you to make a visable diagnosis and do not forget how long it is occasionally necessary to wait. During this obscure period you should constantly keep in mind certain facts which will lead you through the difficulties.

In the first place, among the typhoid states without precise localizations which may be confounded with an incipient typhoid fever, you will be able to eliminate also completely, *a priori*, those which set in suddenly as gastric fever, the grippe, typhus, certain forms of malaria, herpetic and hysteric fever.

In gastric fever vomiting is much more frequent and albuminuria less constant than in typhoid. In the grippe the temperature in the evening of the second or third day reaches 40° and even more; the profuse sweats occupy an important place while they are exceptional, in typhoid fever (except in the sudoral form of Professor Jaccoud). In the grippe, the urine more frequently contains an abundance of urobiline. Yet this disease and typhoid fever may coexist in the same person and develop parallelly. Professor Potain has called attention to this combination of which I have shown you every autumn several examples. With us the epidemics of grippe rage ordinarily in the fall months at about the time when the typhoid epidemics are inclined to diminish, so that our hospital often contains several cases of typhoid and the grippe at the same time. At a given moment it is possible to distinguish in patients the existence of signs common to the two diseases, but in the commencement, the distinction is by far not marked. Not to withdraw too far from the special point under consideration I shall simply state that usually it is the grippe which begins and even may persist after subsidence of the typhoid fever.

Typhus is to be differentiated not only by the appearance as an epidemic and the greater suddenness of its beginning, but also by the deep stupor which it characteristically produces. You know that for several years it seems to have acclimated itself here so that it is well to think of it.

There are also continued forms of intermalarial fevers as well as there are typhoids which affect an intermittent type; here the therapeutic test with quinine and the presence of Laveran's hematozoa in the blood will decide. The same holds good in those cases where the two diseases are associated, typho-malarial fever.

Herpetic fever when the eruption is confined to certain regions of the body, especially the genitals, may also simulate typhoid. Therefore, once more let me tell you always to examine your patients as our fathers said *e capite ad calcem*.

In hysteric fever the urine may remain abundant and clear (Hanot et Boix) and present the inversion of the phosphates as pointed out by Cathelineau and Gilles de la Tourette.

Do not forget that acute osteomyelitis usually sets in suddenly with a profound typhoid state without any definite local symptoms; cerebro-spinal meningitis nearly always bursts forth, all at once, with chills and a fever, with an initial temperature of 39-40° from the first day.

Let us now pass on to a second group of typhoid states which set in more insidiously and slowly.

Firstly, there is acute granular tuberculosis where, from the beginning, one observes fine and fleeting râles in the lungs, while in typhoid fever the pulmorary signs only are seen after the thermic curve is definitely established and then as sibilant

râles. If the râles have not already appeared the fever is active, in acute miliary tuberculosis, and often presenting the inverse type as described by Brunicke as characteristic of acute tuberculosis and in typho-bacillosis there is a disassociation between the pulse and temperature as pointed out by Landouzy. Often from the very beginning the pulse in typhoid is slower, while in acute tuberculosis it is accelerated.

Only very exceptionally is acute phthisis to be diagnosed by the discovery of tubercular granulations in the choroid, by the ophthalmoscope. Remember again, that acute miliary tuberculosis is much rarer than typhoid. Nevertheless, in a general way, it may be stated that the germinative period of all the great acute infections as tuberculosis, typhoid fever, syphilis can not be distinguished the one from the other, even phthisis and acute typhoid fever lack special distinguishing signs. At this period bacteriological examination of the blood will not give the result that it will later. Read in this regard the work of Villomin, where the illustrious physician emphasizes the resemblance of acute tuberculosis and beginning typhoid fever; he shows that they appear to be two modalities of the same general infection. Very able diagnosticians have taken a fever which might be called presyphilitic for a typhoid.

When you have passed in review those morbid states which I have enumerated, you might think also of a typhoid state dependent upon trichinosis or farcy.

In 1874, at the Hôpital Cochin, I saw a farrier who had been sent in by a physician in the city, as affected with typhoid fever. The disease had begun suddenly with chills, fever and headache; several days later the characteristic abscesses of farcy appeared.

There are besides acute cryptogenic infections of which the pathogenic microbe has not yet been determined. The clinician will finish by having impressed upon his eye and mind the physiognomy of the general infection, but what is the hidden germ which is destroying the organism? That is the difficulty which only clinical experience can solve, yet it does not always succeed. At other times the typhoid state is subordinate and dependent upon an acute and local lesion which is primary and predominant as in endocarditis, nephritis, typhlitis or meningitis. An attentive examination will enable one to distinguish the cause. You will have observed that during this entire discussion I have not referred a single time to the value of dicrotism of the pulse, enlargement of the spleen, the detection of Eberth's bacillus in the feces, urine or spleen.

Remember that this is only a question of the diagnosis of the disease at the beginning. Now, I cannot tell you whether the dicrotism is to be perceived in the prodromic period, or just before the period of ascending temperature, or how much time before. This will vary according to the case. Besides, dicrotism is observed in other infectious diseases, yet it is especially noticed in typhoid fever. Puncture of the spleen is not a practicable proceedure and the bacilli in the feces are said by Chantemesse to be difficult of recognition before ulceration sets in. Besides the bacteriologists differ on this point. In the feces of typhoid patients, Gaffky, Di Vesica, Pfuhl, Eisenberg, Rodet and Roux, Redtenbacher, etc., never were able to demonstrate by cultures, the presence of Eberth's bacillus; it was found several times by Pfeiffer, Seitz, Merkel and Goldschmidt; Villschour and Karlinski have never been able to isolate it before the second week. Chantemesse says that one will commence to meet with it from the tenth to the twentieth day.

Habitually, in typhoid fever, the spleen is increased in volume but it is not always so. Last week at the necropsy of the woman lying in the thirteenth bed of the Grisolle ward, who died on the twentieth day of typhoid fever, during which course we discovered a suppurating thyroiditis containing Eberth's bacillus, we did not find the spleen much enlarged; it weighed 205 grammes, measured ten centimetres in length and six in breadth.

On the other hand, an enlarged spleen is met with in typhus, also acute tuberculosis, the grippe and during the fever preceeding syphilis, as my regretted friend Quinquad demonstrated.

In several cases in the prodromic period of typhoid I have observed most frequently I was unable to determine if the organ was enlarged. It must be admitted that an increase in volume of the spleen is not always to be made out; though the German writers often speak of the spleen as

easily to be felt, percussion will furnish you with the most precise indications. Professor Peter laid great stress upon the pain provoked by percussion of the splenic region; that is a sign of infection but is not distinctive. Never forget when you have made out an increase in volume of the spleen, of asking whether the patient has ever lived in a malarial district or has had the malaria, for sometimes this is the only sign of palustral infection.

Since Dr. Vallin's monograph appeared, several cases of afebrile typhoid have been reported where the prodromic stage, the invasion and stage of full developement are thrown into one uniform course, without characteristics and not without peril. At the beginning it presents nothing particular, but it must be kept in mind that one does not confuse a feverless typhoid in full blast with a characteristic case having a prolonged prodromic stage. One might easily announce the near convalescence of the case when it is hardly established in its course, or, possibly while it is on the eve of a mortal complication. Beware of apyretic typhoid.

I once saw a young chlorotic girl who had been ailing for fifteen days without appreciable fever; she was livid, emaciated, no longer able to be on her feet; she was seized with epistaxis and metrorrhagia. A diagnosis of grave chlorosis from pernicious anemia was made. Death took place one night and the necropsy revealed Peyer's patches in the intestine to be ulcerated, with intestinal perforation and subacute peritonitis.

Another time I was called, with three of my colleagues, to a lady aged about sixty, who had lost a daughter from typhoid fever. After her death she fell into a state of profound depression which was thought due to her sorrow. She was abed, motionless and pale. It was a question whether she was not infected at the same time as her daughter who lived with her. But the rectal temperature never reached 38° C.; besides we could not discover any "rash," and a very thick layer of abdominal fat prevented an examination of the spleen. We therefore hesitated at a diagnosis when a mortal hemorrhage from the intestines put an end to the disease. In typhoid fever without elevation of temperature, all chronological distinguishing features are wiped out and one is obliged to wander about without a guide.

I have shown you the first difficulties which will present themselves to you. Though the prodromic stage may be prolonged it may, on the contrary, last but a few days. The condition of the patient aggravates, the weakness increases, headache remains intolerable and is often accompanied by epistaxis; to be about becomes impossible, diarrhœa appears, the nights are passed without sleep and restlessly with some delirium, the fever rises, the pulse becomes dicrotic, the tongue dry, the belly tympanitic, the spleen swells and albumen appears in the urine. The picture is then characteristic, especially as I repeat, if it be a young man or a young girl who has but a short time before come to Paris and an epidemic is raging. I emphasize these words, *young man, young woman* for, according to the age, the picture will change.

Thus in children, on account of the particular sensitiveness of the nervous system, the disease often begins with delirium and convulsions which might lead one to think of a meningitis, or by abdominal pain and vomiting, which might induce one to diagnose peritonitis. In old persons the commencement is often insidious, most generally without headache, without epistaxis, with abdominal symptoms and almost without fever.

Even in the ordinary cases of the young man and the young woman one may encounter another difficulty. Sometimes the disease will begin with a maximum of concentration of the morbid agent or by a localization in some other region than the intestine, a sort of heterotopia.

In several cases reported by Drs. Jaccoud, Duguet, Lecorché, the affection began by a tonsillitis and it was only later with the appearance of characteristic symptoms that it was recognized that a masked typhoid fever was developing. I had seen just such a confusing case during the last year of my time as interne, and the circumstances remain graven into my mind.

One of my friends was seized with an intense tonsillitis; nevertheless he continued at his work in the hospital. For about two weeks we saw him pale and wan, stretched out every afternoon in the easy chair of the watch-room taking with

difficulty a few teaspoonfuls of porridge. He only complained of his throat, which seemed to explain everything. Finally, unable to bear up longer, he left Paris to go to his parents. The same day of his arrival there, after the first meal with his family, he died of intestinal perforation.

At other times it is pneumonia which opens the scene. Professor Potain, in his lectures, has pointed out the mode of its beginning. Gerhardt and Lépine have also published several cases under the name of pneumo-typhoid. I have also recorded a typical observation, in 1884, in the thesis of Dr. Mulette. In a case reported by Dr. Lecorché, a pleurisy seemed to have been the initial phenomenon. Besides, do not forget that cerebral symptoms may burst forth with great violence during the first days under the form of mania. Patients have been sent to asylums for maniacal symptoms which masked a typhoid fever. Soon the disease was manifest enough, while the mental complication went on to decrease or disappear. Take care not to fall into such an error which may be so disastrous in many ways. Quite a while ago I observed two cases of typhoid fever commencing by melancholy and delirium de grandeur. You may find them in Dr. Barbelet's thesis (1874). One of these was a young woman who accused herself of having drowned her two children, groaning without cessation and demanding mercy; the other was a man who thought himself director of the opera and distributed tickets to boxes to those about him. These two patients had been sent to the Sainte-Anne Asylum where the diagnosis was rectified a little latter. Dr. Bucquoy and I, in our monograph on the delirium of typhoid fever, have treated of these pseudo-manias of the beginning of typhoid fever.

Without having exhausted the subject of typhoid fever, I think I have dwelt long enough on the subject to teach you prudence and reserve.

ACUTE BRONCHITIS IN CHILDREN.

W. B. MOORE, M.D., WOODBURN, N. C.

Bronchitis of infants has, it seems to me, enough of interest to be spoken of at some length, but such is not my purpose. I have noticed that this subject has been somewhat neglected in medical journals.

Bronchitis occurs both as a primary and secondary disease. It is primarily caused by sudden change of temperature, from warm to cold, exposure to currents of air and the carrying of children, insufficiently clothed, from heated rooms into the open air, also throwing off the bed clothes during sleep.

The causes of secondary bronchitis are obviously the diseases in connection with which it occurs.

Bronchitis is generally bilateral except when due to tubercles or to pneumonia, then it is often confined to the tubes nearest to the diseased area.

Of the symptoms are flushed face, headache, acceleration of the pulse, fretfulness, with lessening of the appetite, and increased respiration according to the intensity of the disease.

On auscultation are heard coarse râles. At first sibilant and sonorous râles, at which times the secretion of mucous is scanty. The cough, in the commencement is for the same reason dry. It gets looser by the second or third day. Unless the child has reached the age of four or five years, expectoration does not take place; phlegm is usually found in the stools in either case; the color of the stools may also be changed to a greenish hue from an improper diet or germ, with a bad odor attending the stool.

Treatment should be both external and internal.

A poultice should be applied to the chest. The one I have most frequently used is made of wheat bran, about one and a half pints, to which should be added enough boiling water to steam, placing the bran first in a heated vessel. When thoroughly steamed put into a muslin bag. On the side to be placed next the skin, sprinkle spirits of camphor. Use as hot as it can be borne, first testing it

COMMUNICATIONS.

THREE OPERATIONS FOR EXTRACTION OF CATARACT—ONE ARTIFICIAL RIPENING OF SENILE CATARACT.*

JAMES MOORES BALL,† M.D.

I always extract without it, unless a specific reason exists for the making of an iridectomy. This is a more difficult operation but, if all goes well, the patient is left with a nice round pupil, in place of the large coloboma of an iridectomy.

CASE I. The first patient, a colored woman who does not know her age, presents bilateral cataract. Each eye is ready for operation so far as the ripeness of the lenses is concerned. We will operate upon the left eye. The patient's face has been thoroughly cleansed, the conjunctival cul-de-sac washed with a 1:2000 solution of bichloride, and cocaine has been instilled. We insert the Knapp speculum; you will notice the palpebral opening is unusually small, causing the woman to look like a Mongolian. The distance from the inner canthus to the root of the nose is greater than usual, and the eye is small. This state of affairs will make the operation more difficult than usual. Not being ambidextrous it will be necessary for me to stand in front of her in operating upon the left eye.‡ A few instruments are now handed to my assistant and we begin. The eyeball is turned downward by forceps held in my left hand and a small Graefe cataract knife is passed through the apparent corneo-scleral junction and brought out at a point opposite. Now by a gentle sawing motion the cut is made, the knife is laid aside, a cystitome of the angular variety is passed into the eye, turned on its axis, and made to incise the anterior capsule of the lens. Now, stepping behind the patient, I take the cataract spoon in one hand and a spatula in the other and deliver the lens. You will notice that considerable pressure is required—more than in the operation with an iridectomy, since the resistance of the iris must be overcome. The iris, by its own elasticity, withdraws into the eye, but the pupil is not in the center of the cornea. After cleansing the eye of all fragments of cortex we will gently stroke the iris back into place, leaving it with a central pupil. The speculum is now removed, the lid is closed gently and a moist dressing of bichloride applied. The other eye will be bandaged.

CASE II. This man, Mr. H., aged sixty, a German, was operated on some time ago by some one who removed a cataract from his right eye; the result was not satisfactory and he wants me to remove the opaque lens on the left side. He cannot count figures but readily tells the location of the windows. Having him well prepared for the operation I will now remove the cataract. This is a much easier case upon which to operate. The eye is of good size, the palpebral fissure of normal width, and everything promises a good result. You notice that I pick up another knife, it being my practice never to use a cataract knife the second time without sharpening it. The knife and other instruments are dipped into boiling water for a moment. I pass the knife in the usual manner and the section is made without a hitch, and those who are near to the patient will notice how the cornea collapses after the cut is made. The capsule is now ruptured in the usual manner and the delivery effected without difficulty. The dressing of this eye will be similar to that of Case I.

CASE III. This old negro, like many of his class, does not know his age, but he appears to be about seventy. He has been blind in both eyes for three years. Each lens looks white like milk, and it is in such eyes that we find Morgagnian cataracts—one with a hard nucleus sur-

* Clinical Lecture.

† Professor of Ophthalmology and Otology in the St. Louis College of Physicians and Surgeons; President of the Tri-State Medical Society of Iowa, Illinois and Missouri.

‡ The writer has recently learned to extract cataracts with his left hand.

rounded by liquid. You will observe here a marked arcus senilis. This, however, has no bearing upon the healing of the wound. The usual incision is made, only smaller than in the preceding cases; the capsule is ruptured and now you see the milky substance running out of the capsule. It is a case of Morgagnian cataract. The hard part of the lens is delivered through the natural pupil. In this case the iris remains in contact with the lips of the wound. The pupil has been cleaned of all débris, and the iris has been stroked back into place, but immediately prolapses. Perhaps the use of eserine solution would keep it in place, but I will not take any chances. The iris is cut off, the angles of the iris are freed from the corneal wound and the usual dressing applied.

Case IV. This man has noticed failing vision for two years. Inspection shows bilateral immature cataract. He readily counts fingers at six feet. It is in such cases, where both lenses are becoming opaque slowly, that an operation for artificial ripening is indicated. There are many methods of procedure, all of which have been advanced since 1881, when Foerster, of Breslau, began his operations. He was in the habit of making an indectomy, after which massage of the lens was made by a strabismus hook, the collapsed cornea intervening between the lens and hook. It is an indirect method. The operation which I prefer, and which bears Bettman's name, is a direct trituration. The pupil is widely dilated by atropine, the usual antiseptic and cocaine solutions applied, and we commence. I introduce a keratome into the anterior chamber, not for the purpose of performing an iridectomy, but simply to make an opening. Through this opening a spatula is passed, and by a concentric motion the anterior capsule of the lens is triturated. Care must be taken lest we rupture the suspensory ligament and get inflammatory symptoms. We desire to break up some of the fibres of the capsule so that some of the aqueous humor may come in contact with the lens. The lens will absorb the aqueous, swell up and ripen in a few weeks. Hence, such cataracts which otherwise might require years for maturity, will often be ripened and removed within five or six weeks. The spatula is withdrawn, a few more drops of atropine instilled and the eye is bandaged. The nurse is instructed to apply atropine twice a day and the bichloride dressing is used.

As you see, I have made no attempt to hurry. While everything is properly planned and systematically executed, an oculist can remove a half dozen cataracts within the limit of an ordinary clinic hour.

Dietetics of Chronic Heart Diseases.

Dr. Glax (*Deutsche Med. Zeitung*) calls attention to the value of decreasing the ingestion of fluids in the management of chronic diseases of the heart, a view which was warmly advocated by Oertel and others, but which has been too much neglected. If one carefully measure the quantity of fluid drunk and the urine excreted them one will remark a striking difference, for a certain portion of this fluid is retained to burden the heart's action. With withdrawal of a portion of the usual quantity of the fluid taken a continuous improvement will be noticed. From a study of this question in a large number of cases, which extended not only over months but even four to five years, he comes to the following conclusions:

1. Restriction of the quantity of ingested fluids is one of the most important measures in the treatment of chronic heart diseases, and of itself is often sufficient to bring about compensation.

2. In many cases where cardiac stimulants have failed their action will become apparent as soon as regulation of the quantity of fluid is carried out.

Care should be taken in reducing the quantity of water, as that might give rise to grave disturbances. Heart patients are especially prone to drink more than normal, which, by filling the stomach and pressing upon the diaphragm, obstructs heart action.

Rest After a Meal.

No work of any kind should be done in the hour after dinner. After any substantial meal, observe, you need all your vital force for the beginning of digestion. For my part, I always go to sleep after dinner, and sleep for exactly an hour, if people will only stay away; and I am much fond of the people who keep away from me at that time than I am of the people who visit me.—*Edward Everett Hale.—Ex.*

A UNIQUE CASE OF DOUBLE EXTRA-UTERINE PREGNANCY.

J. M. DUFF, M.D., PITTSBURG, PA.

Two years ago this month, I was called to see a woman twenty-eight years of age. She had been married for five years and never had been pregnant. At this time she had not changed for two months. Was complaining of pains in the left iliac region. I found some tumefaction. Upon a more careful bimanual examination, I diagnosed a tumor which was evidently in the left fallopian tube. The presence of this tumor in connection with the fact that she had not menstruated for sixty days, that she had morning sickness to a slight extent and some other signs of pregnancy, led me to diagnose an extra-uterine pregnancy. I advised an operation. She partially consented to it. My friend, Dr. Werder, saw the case with me. I believe he agreed with me in my diagnosis of extra-uterine pregnancy. Shortly after this the lady was suddenly taken ill and I was called in hastily. She had severe pains and a tendency to faintness, but did not entirely faint away. By the time I reached her she was flowing and upon examination I found that the tumor had disappeared from the tube. I could not find it. After this she improved rapidly and in a short time she did not call for any further medical assistance. Occasionally during this time, and subsequently, she had slight pains in the lower portion of the abdomen which were periodical in character until last March when she again missed her changes. About nine weeks after changing she was taken with hemorrhage. I was called in and found she had miscarried. The ovum was expelled from the uterus into the vagina. She got along very well after this up to the 12th of October of this year. On this date her husband came running to my office asking me to hurry to his home, stating that his wife had suddenly been taken ill. It was a very short distance to the house and when I arrived I found her in the water-closet. She was in a semi-comatose condition. Partially collapsed and almost pulseless. I had her removed to her bed; warmth and friction applied and stimulants administered hypodermically. When she recovered her senses she complained of very severe pain in the iliac fossa. She was so tender that it was impossible to make an examination by vagina. Upon further examination, however, I found a tumor in the right fallopian tube. I then got the history that she had missed her changes twice, it being ten weeks since she had menstruated. On the next morning she began to waste slowly. Some discharge of membrane. Some sickness at the stomach. I again diagnosed extra-uterine pregnancy, but in the right side, and insisted upon operation. She would not consent, thinking she would get over it in the same manner as she had the previous one. But she gradually grew worse up until October 18th, when she consented to the operation. She was taken to the South Side Hospital, and assisted by Drs. Kerr, Thomas and other members of the staff, operated.

I found a tumor in the right tube which was almost on the point of rupturing. The tumor had the appearance of a mole pregnancy as we find them in the uterus. On cutting it open we found a small fœtus enclosed in its membrane inside of it, needing no further demonstration that this was a case of extra-uterine pregnancy. We found on the left side another sack which was attached to the fallopian tube and contained some matter which was considered by all who saw it to be placental tissue. It was attached to the bowels by general adhesions; instead of dropping down it was thrown up over the uterus. A small portion of the end of the tube had split open.

The subsequent history of the case is good. There was an uninterrupted recovery. Her temperature after the operation was 101°, but soon became normal. During the third week after the operation some little indiscretion in eating caused the temperature to rise to 100°. She left the hospital last week and went to her home, her general condition being very good. I report this case as a very unique one, involving as it does a double extra-uterine pregnancy.

DEATH RESULTING FROM HEAD INJURY.

C. C. HERSMANN, M.D., PITTSBURG, PA.

Thomas F., aged forty-eight and a half years, I saw in consultation with Dr. P. G. Rossman, and obtained the following history: On March 4, 1887, while on duty as turnkey at the twenty-eighth ward police-station he, was assaulted by a prisoner who struck him several (5) severe blows upon the head, making as many cuts or scalp wounds, rendering him unable to cope with his assailant.

He was removed to the Mercy Hospital, where he remained thirty days, during the first nine of which death was expected at any time. He went to work on the 15th day of the following October. He worked about two weeks when he was compelled to give up. At the end of seven weeks he returned to his work, but after another two weeks was again obliged to lay off. At the end of five more weeks he again went to work and was able to continue for nearly a year. He then laid off with severe pain in the right ankle. Again he worked three months and then was laid off five months with pain in all the extremities, upper and lower. The right side seemed to be particularly involved. From this time to his death he suffered more or less with severe pain in the head. He was able to work only a few days at a time when he would be compelled to lay off on account of severe headache. Thus he dragged through life. Whenever he had sickness with elevation of temperature he was very delirious. On March 6th, 1894, I was called in consultation, as stated in the outset, and found the following conditions: A slight pneumonia, severe congestion of the brain and elevation of temperature with acute delirium, he having to be held in bed. On the 9th I again saw him and found him much the same except a semi-comatose condition had taken the place of delirium. He died within the next twenty-four hours with symptoms of apoplexy.

A post-mortem examination revealed the following conditions: A scar immediately above the left temple 1⅝ inches long, and one in the corresponding region on the right side 1¼ inches long. A scar directly between the parietal bosses in the region of the crown on a line with the longitudinal suture two inches long, and a scar at right angles with and crossing the aboved-name about mid-way, four inches long. The scalp at the crucial scar was adherent to the skull. On attempting to remove the calvarium, the brain and its membranes were so adherent that, be careful as I might, the cerebrum entire was torn from its position and afterwards removed from the scull-cap by breaking up the adhesions.

Pia mater severely congested. On that portion of the brain corresponding to the top of the head, there was a free exudation which was rapidly approaching pus formation. The brain was severely congested throughout, the upper portion of the cord and medulla congested. A considerable meningitis had developed.

An interesting point in this case is the fact that he not only retained his mental faculties, but he was so materially affected whenever undergoing systemic disturbances, that he must have been on the border land of insanity. Another instance in which we see the wonderful power of nature resisting the inevitable to the last.

The party who committed the deed was sentenced and served time for aggravated assault. The medico-legal point is this: Having every evidence that the injury was the cause of death, can the accused be re-arrested and made to answer to the charge of murder?

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

RODERIC C. PENFIELD
Publisher.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, MARCH 9, 1895.

EDITORIAL.

AN OVERCROWDED PROFESSION—THE REMEDY FOR THE EVIL.

Some years ago, there was much editorial amusement over a very ungrammatical letter of indignation which a recent graduate in medicine had written after his failure to pass an examination for appointment to a hospital as interne. In language which was unmistakable in meaning if not correct in form, the doctor asseverated that he had been *defrauded* by the faculty which had graduated him. He was evidently convinced of the justice of the decision of the examining board, for his grievance was that, *knowing his lack of preliminary education*, the faculty had encouraged him to pursue a medical course, had taken his money and had given him the legal right to practice a profession, for which he now realized that he was incompetent. He further accused the faculty of desiring to have just such incompetents in the profession for the sake of obtaining fat consultation fees.

We feel that the ridicule heaped on the writer of this letter was most unjust. Lack of education is a misfortune oftener than it is a fault, and there are thousands of persons who cannot use their own language correctly who are, nevertheless, good citizens in every sense. The fault lay with those agencies which tried to lift the man bodily from that plane on which he could be a useful member of society, to a higher one in which he would not only be out of place but would be in a position to inflict much damage. When one has the manliness to admit that he has made a mistake and that he is not fit for the position he has tried to occupy, he deserves sympathy and respect, not ridicule. In his accusation of his faculty he may or may not have been justified. There are medical professors who deserve the scathing rebuke which this ignorant man has uttered, and there are others who are thoroughly conscientious in their relations with student, colleagues and laity alike.

In this anathema, however, we find the

keynote of the entire theme which we are discussing. Outside the struggle, we have an apathetic laity whose only apparent interest is the fear that the medical profession may do something that will interfere with its inherent right to consort with sectarians and irregulars and to take quack medicine. On the one side, is the rank and file of the profession struggling for a livelihood; on the other, the college faculties, whose members feel but slightly the growing hardships of competition, while they are directly benefited by the prestige of their position. The fees of students may amount to comparatively little in the revenue of college professors, as a considerable attendance is necessary merely to pay the running expenses of the college. The real object of securing a full attendance of students is the greater honor which it will confer on the institution and those connected with it, and the wider territory over which the fame of the faculty will spread.

In a country supplied with a few colleges under state supervision, with faculties chosen impartially and comprising men of pre-eminent qualifications, it would be an easy matter to limit the number of graduates. The present system of semi-private corporations has tendencies which work in a vicious circle. It is possible to select from the profession of almost any city of 200,000 inhabitants, at least three groups of doctors whose average abilities would equal or excel those of the faculty of an average medical college. It would be possible, in addition, to select two or three other groups, lacking somewhat in professional attainments but with greater business acumen and fully awake to the advantages of college professorships. The result is obvious; a combination of brains, business and brass is effected, and a new *University* (*!*) springs into life.

In a certain city is a medical school of fair reputation, abundantly able to supply the needs of the entire territory which it would naturally drain. After a time another college is started, the members of the faculty gladly paying heavy assessments to keep it running. Why? "Because the old school is not adapting itself to newer standards of education," say the faculty of the new one—in public. "Because there are a lot of men here who want to be professors and can't get into the old ring," says one of the new faculty—in private. And yet, the majority of the members of the "new ring" "are men of as great tability as those of the old ring," and have the same right to the gratification of their ambitions. It is no uncommon incident in modern times, to find three or four men competent to fill a position which all want and which only one can have. The result is sad but inevitable. There are individual cases in which influence and money have elevated to superior positions men of inferior qualifications. As a rule, in the case which we are considering, influence and money have simply been the determining factors in choosing between men of equal ability. The profession as a whole cannot blame, and should not envy, the faculties of colleges for availing themselves of the better fortune presenting. We need not consider a man dishonest because he is a stockholder in a railroad that charges three cents a mile; but, although we respect the man, it is none the less sound policy to secure legislation which shall reduce the milage rate. So, in the case of medical faculties, it is useless to criticize or to intimate that the members occupy their positions through pull, or to draw comparisons with political rings. The men themselves are usually worthy of respect and even admiration. Human nature simply is not enough altruistic for any medical faculty to close their institution and disband because they see the profession oversupplied with incompetent competitors.

The only logical and manly course for the profession to adopt, is to endeavor to

secure proper legislation which shall serve to limit the total graduating list, and thus to throw the brunt of competition upon the college faculties. The whole problem would then soon be satisfactorily settled by the survival of the fittest and the destruction of the weaker and inefficiently equipped colleges. Such a course, moreover, could not be openly combatted save by the avowal of selfish motives and of a disposition to debase the standards of the profession, while it would receive, even now, the cordial support of all the better class of medical colleges.

Fortunately, the issue is not merely an economic one. The medical profession is overcrowded but not with good physicians. Of the raw recruits who are pushing their way to the front, a relatively small proportion are qualified for the service. The solution of the problem does not necessitate the exclusion of a single worthy man; it does not demand the establishment of an unreasonably high scale of qualification; it requires merely that the coming physician shall have a passable education. The issue is one on which depends, not only the welfare of the medical profession, but to a high degree the health and chances of longevity of the entire population. If the issue can once be fairly comprehended by the physicians of the country and fully presented to the laity, the solution ought to be an easy matter.

ABSTRACTS.

THE SURGERY OF HYPERTROPHIED PROSTATE.*

THOMAS EAGLESON GORDON, M.B., B.Ch., Univ. Dubl.

The subject I have chosen for my address is the Surgery of Hypertrophied Prostate. It will, however, be convenient in the first instance, to briefly review [illegible] is known of the development, anatomy and function of the normal gland as [illegible] at least, as these are of surgical interest or importance.

If the abdomen of an early embryo is opened there will be seen, on either side of the middle line, in the lumbar region, two long vascular prominences. These are the Wolffian bodies structures composed of glomeruli and tubes similar to those found in the permanent kidney.

Leading from the Wolffian bodies there will be seen the Wolffian ducts and these pass downwards to open into the urogenital sinus.

This sinus is merely the lower portion of the spindle of the allantois; the upper part of the spindle, it will be remembered, forms the urinary bladder.

Lying internal to the Wolffian body is another structure, the genital organ; and coursing downwards, alongside the Wolffian duct, is the duct of Müller, which opens like it into the urogenital sinus. The lower part of the duct becomes fused with its fellow to form a single tube. The upper end is open into the peritoneal cavity.

These structures—Wolffian body and duct, genital organ, and duct of Müller—are the rudiments of nearly all the future genital system of both sexes. In the male, the testis is developed from the genital organ; from the Wolffian body and its duct are derived the vasa efferentia tube of the epididymis and vas deferens.

The urogenital sinus becomes the first portion of the urethra. The ducts of Müller undergo atrophy almost to annihilation. But their upper part persists as the hydatid of the epididymis, and the extreme lower united parts are represented in the uterus masculinus or prostatic vesicle. Very different is the fate of

*The Presidential Address to the University Biological Association, Dublin, 1894.

the duct of Müller in the female. Here the upper part remains as the Fallopian tube, and the remainder, the united part, forms the uterus and vagina.

It will thus be seen that the uterus masculinus must be the homologue of the uterus and vagina, or of some parts of them. It seems to be the opinion of the best modern embryologists that it is most probably the homologue of the vagina alone.

The development of the prostate itself has been lately specially worked out by Griffiths of Cambridge. The conclusions he arrives at are these—The tubules are derived from the prostatic sinuses on either side of the verumontanum—*i.e*, from that portion of the urethra which, as we have seen, is formed from the urogenital sinus.

As the tubes extend backwards they carry with them a prolongation of the external circular fibres of this part of the urethra, and this muscular tissue is seen in the fœtus spread out in slender fasciculi investing the developing tubes.

As the gland grows, it extends outwards and forwards, but the glandular part, as a rule, does not fuse in the middle line, the continuity of structure being effected by muscular tissue only.

The prostate, it will then be seen, has no developmental connection with the ducts of Müller. The uterus masculinus is no part of the prostate, but merely becomes imbedded in it in its lateral and forward growth. The prostate is not the homologue of the uterus, and we have seen that even the uterus masculinus is probably the homologue, not of the uterus but of the vagina only.

I need occupy only a very few minutes in describing the adult gland, particularly as I have some lantern slides to show, which, with Professor Cunningham's kind permission, I have been enabled to obtain from his frozen sections of the pelvis.

The prostate is composed of gland and unstriped muscle, the latter forming nearly three-fourths of the whole. The glandular part is made up of branching tubes, ending in tubular alveoli lined with columnar epithelial cells.

The average weight of the normal gland is about six drachms. It measures in its long axis, which is nearly vertical, about one and a-quarter inches, and it is about one and a-half inches in width. In form the prostate is roughly conical, and is usually described as having three lobes. The existence of the middle lobe has been questioned, but Griffiths has shown that it certainly does exist in a considerable number of cases. The base of the prostate rests against the bladder, about the internal urethral orifice. The term neck, as applied to this region of the bladder, is objectionable, as no constriction occurs about the urethral opening such as this term would seem to imply. The urethra traverses the gland at about its centre, and I would remind you that this portion of the urethra is almost vertical in direction. In front the prostate is separated from the lower part of the symphysis by a distance of about three-quarters of an inch, and behind is in close relation with the second part of the rectum. It is placed at a much higher level in the pelvis than is, I think, usually appreciated, its base being opposite some point on the upper half of the symphysis.

The gland is firmly fixed in position by the fascial connections of its capsule, so that it only sinks to a slight extent when the bladder is distended. If it is desirable to overcome the slight fall, for operative purposes, it can be prevented by a moderate distension of the rectum. The presence of this fixed support about the orifice of the urethra will easily explain the occurrence of a post-prostatic pouch when there is any cause of obstruction to the urinary outflow. In prostatic cases it will, of course, attain its greatest degree, because the sinking of the bladder behind the urethral orifice will be accompanied by a raising of the orifice itself, depending on the upward direction of the enlargement.

Within the capsule is the prostatic venous plexus. These veins become dilated and varicose in old age, and their valves disappear. Immediately beneath the mucous membrane of the urethra there is another smaller plexus which undergoes similar changes. These veins communicate freely with the hemorrhoidal and other veins in the neighborhood, and this fact, taken in conjunction with the absence of valves, explains the frequent congestions of the prostate—congestion which is sometimes sufficient to cause complete retention. The varicose submucous plexus is of interest as explaining the occasional occurrence of severe hemorrhage after the passage of instruments in these cases.

Although surrounded in this way by venous plexuses, the blood-supply of the prostate itself is remarkably small, and unless the venous plexuses are encroached on, large portions may be removed without causing severe hemorrhage.

The most important point to be determined in connection with the function of the prostate is whether it is or is not essentially a sexual organ. The solution of this problem has been arrived at by observations of prostatic changes in certain of the lower animals, which have distinct periods of sexual rest and sexual activity.

These observations were first made by John Hunter many years ago. He writes as follows:—"In the mole the prostate gland in winter is hardly discernible, but in the spring becomes very large and filled with mucus." This fact was confirmed by Sir R. Owen, and during the last few years by Griffiths. Griffiths' observations are of particular interest, since they include microscopic examinations. I need not delay to describe them in detail. Suffice it to say, that they fully confirm John Hunter's early observations—that they show that the prostate undergoes an enormous increase in size during the breeding season, and that this increase is accompanied by important changes in the shape and number of the epithelial cells lining the gland tubes, and by equally marked changes in the muscular stroma. These interesting facts, I think, conclusively show that the functional activity of the prostate in these animals is closely dependent on the functional activity of the testes, and this relationship would seem to justify us in regarding the prostate as an accessory sexual gland.

This conclusion has received confirmation from the effects on the prostate which have been observed to follow castration in many animals. In Hunter's works the following statements occur:—"The prostate and Cowper's glands, and those of the urethra in the perfect male, are soft and bulky, and the secretion salt to the taste. In the castrated animal these are small, flabby, tough, and ligamentous, and have little secretion. Especially marked is this change when the animal is castrated when young." These observations have received striking confirmation by Griffiths and White, and it has now been absolutely proved that the prostate will undergo atrophy whether the animals are castrated when young or when they have attained to adult age. The experiments conducted for White are particularly interesting.

The average weight of the prostate was first determined by experiments on 35 dogs. Taking the average weight in dogs weighing 14 to 16 kilos. as 15 grammes—in one case, 17 days after castration, the prostate was found to weigh only 5½ grammes instead of 15. In another dog, in which the average weight of prostate relative to its weight was 19 grammes, it weighed only 2½ grammes about a month after castration. There were, in all, twenty-four experiments performed, and in every case the results were equally remarkable. Microscopic examinations were made in each, and showed atrophy of both glandular and muscular elements.

The prostate is then undoubtedly a sexual organ, and recent experiments tend to show that it is not only accessory but essential to fertilization. This fact has been proved by experimental removal of the prostate. In the animals so treated the power of copulation remained, but they were incapable of reproduction of their species. Such being the case in the lower animals, one might, with tolerable safety, conclude that the prostate has a like function in man, and that castration would lead to either nondevelopment or atrophy. The direct evidence is, unfortunately, very unsatisfactory, and is almost confined to the case of a few eunuchs. We must, then, speak with caution, but as far as these imperfect observations go they confirm the results which we would in the first instance have anticipated.

I think it would be very unsafe to dogmatise concerning the exact part which the prostatic secretion takes in fertilization.

Föroringer is of the opinion that its function is to awaken the latent vitality of the spermatozoa. He found by actual experiment that the addition of prostatic fluid to testicular secretion caused movements in spermatozoa previously quiescent.

It remains to consider the relation of the prostate to micturition. This long-vexed question concerning the sphincter of the bladder can scarcely be said to be definitely set at rest. The true voluntary sphincter of the bladder is probably situated near the apex of the prostate, and

consists of a circular band of tranversely striated muscle, named after its discoverer, the external sphincter of Henle. The portion of the urethra above this may, perhaps, almost be looked upon as part of the bladder, but unless there is considerable urinary tension it is kept closed by the elastic pressure of the prostate which surrounds it.

Leaving this necessarily somewhat lengthy introductory matter, I will proceed to the discussion of the more purely surgical part of the subject.

The enlargement which I have now to speak of is almost certainly a glandular hypertrophy. The fibrous form may be regarded as merely a later atrophic stage. Of the cause of this enlargement absolutely nothing is known. We cannot even state with certainty its time relation to the cessation of sexual function, for, although the testes may become inactive at fifty, it is undoubtedly true that they may continue active until seventy or later. A discussion of the numerous theories would be mere waste of time, but I cannot resist a short reference to one, that of Mr. Reginald Harrison. He endeavors to prove that the enlargement is a compensatory change formed to oppose a sinking of the bladder behind the prostate, which he says, tends to occur in old age.

To support such an extraordinary, so improbable, a theory, one would expect to find very convincing proofs that this sinking of the bladder does occur—such proofs are not forthcoming. Further, the enlargement is not fibrous, nor even muscular, but, as I have said, almost certainly glandular; and even Mr. Harrison will hardly think it possible that a gland should increase in size in order to support some superimposed structure.

Again, in certain of the lower animals—*e. g.*, dogs—this enlargement occurs, and in them the axis of urinary pressure is entirely different. The only difficulty which Mr. Harrison himself recognizes is the occurrence of those masses which sometimes grow up into the bladder. This he explains by the following amazing statement:—"I would speak of these as the upheavals of a frequently contracting muscular ring." My respect for Mr. Harrison as a distinguished surgeon will prevent me expressing what I think of this volcanic utterance. It is surely a *reductio ad absurdum*, and I would have made no reference to the theory were it not an excellent example of the dangers attending speculation on so obscure a subject.

Before discussing the operations proposed for the relief of prostatic hypertrophy, it is scarcely necessary to make the statement that a very large majority of all such cases require no treatment other than properly conducted catheterism, and such a regulation of the general mode of life of the patient as may be best suited to his condition. Setting aside these cases there remains a minority in whom these simple methods are no longer sufficient. I will briefly consider what indications we have that such a stage has been arrived at. First in importance is frequency of micturition. The principal causes of such frequency are an increasing proportion of residual urine, cystitis from whatever cause, and, thirdly contracted bladder. This latter condition, though apparently uncommon, is one of great importance, since it may be regarded as a certain indication for operative interference. A patient in this condition, as Sir H. Thompson puts it, lives for little else than to pass his catheter, and has arrived at a stage that is the almost certain prelude of approaching death.

In addition to extreme frequency and conditions, such as cystitis, specially associated with it, I wish to remind you of certain other indications of the approaching end to catheter life. One is increasing difficulty in the passage of instruments due to the particular nature of the growth. Another is repeated hemorrhages. A third the presence of a calculus.

The occurrence of these signs may be regarded as the advent of a further stage in the life of the patient with prostatic hypertrophy. The further course, if untreated, is one of continuous decline. It is marked by signs of general deterioration—such as progressive emaciation, loss of appetite, and thirst with dry and coated tongue; and at times by graver symptoms as a remitting fever or recurring rigors. These, when combined with signs of local deterioration—increasing frequeney, increasing proportion of residual urine, and at times, it may be absolute retention—complete a picture only too familiar and point with certainty to the coming of the death.

That this sequence of events may be expected when the signs we have mentioned become manifest, has long been recognized by surgeons; and it will be convenient to briefly consider, first, what have been considered the limits of surgery in these cases up to recent times, as this will enable us to better estimate the degree of progress that has since been made.

It is only during the last few years that, for this further stage, any operation has been undertaken of a radical nature. It is indeed true that every now and then operators, who either held a great reputation or wished to obtain such, proposed and practised cutting operations on the prostate, but none of these received universal sanction and they do not even receive mention in standard text books of surgery. The palliative measure most deserving of attention is perineal drainage. This operation was brought prominently before the profession by Sir H. Thompson some ten years ago, and, needless to say, is based on sound surgical principles. By getting rid of the necessity for frequent catheterism, it furnishes rest for the patient, and by affording excellent drainage in *most* cases it gives rest to the bladder and urethra and does much for the relief or cure of cystitis.

But while fully recognizing the excellent results obtained in many cases, we cannot overlook certain limitations to its usefulness.

1. It is unlikely to afford sufficient drainage if there is much post-prostatic pouching of the bladder.

2. If the prostatic urethra is much lengthened it cannot allow of digital exploration of the bladder—a calculus might in these cases easily be overlooked.

3. If catheterism has been difficult on account of the form which the enlargement has taken, this difficulty cannot but again present itself when the perineal wound has closed.

That there are such limitations is, of course, fully recognized by Thompson, and he has recommended another operation as a substitute for it or as a sequel to it. This operation is suprapubic cystotomy for exploration purposes, and the subsequent maintenance of a permanent opening, in which is fixed a shielded silver catheter. Sir H. Thompson gives some details of a case thus operated on as a proof of its success.

This was "an advanced case of constant and painful catheterism." A suprapubic exploration was carried out in 1886, "and dense fibrinous deposit and much adhering phosphatic grit were successfully removed," and the patient was able to walk abroad in about a month. Now mark his condition: he was able to walk three or four miles a day, was free from pain, and his general health was on the whole good, but he had constantly to wear his silver cannula, and supplemented his own faulty anatomy with the ordinary urinal worn by persons requiring such a convenience. Instead of the simple method of relief which normally precedes sleep, this unfortunate man had to wash out a large part of his urinary tract. First, he removed and washed his cannula, then, I suppose, he cleaned out his rubber bag, and, lastly, the relics of his bladder.

Now I have no doubt this man's condition was much improved, but, I think, he surely had no elysium here on earth, and would welcome the time when he would be called upon to shuffle off this mortal coil and his artificial bladder for ever.

I have endeavored to state, as clearly and briefly as I could, the most which a surgeon can expect to do for these advanced prostatics if he keeps to the beaten tracks of what I will call orthodox surgery; and I will now lay before you the newer operations performed and the results achieved by men, some of whom I am pleased to look upon as pioneers of nineteenth century surgery.

First amongst such operations I will place suprapubic prostatectomy. For the introduction of this operation surgery is certainly indebted to M'Gill, of Leeds; for, although isolated instances of its performance occurred from time to time, it never received any serious consideration until its claims were urged by M'Gill in his Leeds Address before the Medical Association in 1889.

It would be beside my purpose to here discuss the technique of the operation. Suffice it to say, that an opening is made above the pubes. The interior of the bladder is carefully examined and the growth removed. The object in all cases is, first, to remove any protruding intravesical growth, and, secondly, to provide a low-level urethra which will be capable of draining a post-prostatic pouch. The

first portion of the urethra should be digitally examined, and if it is necessary to extend the operation to this region it is considered well to add to the supra-pubic opening another in the perineum to drain this portion of the urethra.

This account, though brief and imperfect, will, I think, sufficiently show that this supra-pubic prostatectomy is an operation of the greatest possible gravity. It matters little what published statistics show; common sense, which is often a better guide than statistics, will clearly show to any man possessed of it, that this is an operation attended with the greatest possible risks to life, especially in the case of such patients as these. Granting this, it is evident that to justify its performance its advocates must show us results better than can be obtained by other safer means. Particularly they must show—

1. That the obstruction will not recur in even a large minority of cases.

2. That the function of micturition will be restored in a fair proportion of cases.

3. Or, failing this, that the patient will be once more able to resume his catheter life with far greater comfort and success than previously.

As regards recurrence, it is satisfactory to find only one instance of it in ninety-four cases recorded by Maunsell Moullin; and any opportunities which have arisen of subsequent examination have confirmed clinical results.

Concerning the restoration of micturition by this or other forms of prostatectomy, Sir H. Thompson makes the following statement in his Clinical Lectures in 1888, not since, as far as I know, contradicted: —"I have long wished to see this sight, and have travelled considerable distances abroad and elsewhere expressly seeking it, but at present without success."

Now, it requires most convincing, overwhelming evidence to overthrow this opinion stated by the greatest living master of urinary surgery. I believe such evidence is forthcoming. I cannot discuss the matter at length, but I would instance particularly several of M'Gill's cases published since Thompson's lecture, a case recorded by Buxton Browne, and again, at all events, one of Mayo Robson's twelve cases.

But apart from this very severe test, the restoration of the function of micturition, this operation of supra-pubic prostatectomy has shown such excellent results as to justify its holding a definite place in surgery. I think we should, however, insist that as an operation it must be confined to a very limited class of cases—to men who are no longer able to live with the aid of catheterism alone, but who still possess sufficient strength to undergo a major operation, an operation likely to be attended with severe shock, and, it may be, considerable loss of blood. For the remainder—the far advanced cases—there is, I believe, at present one chance, and one only, and that a perineal section.

I have not thought it necessary to consider other procedures which are, for the most part, only modifications of perineal section; but quite recently an entirely novel operation has been proposed which I must now refer to. The operation cannot at present be said to hold any definite position in surgery; but the very fact of its being on its trial will, I hope, give it the greater degree of interest. This operation is double castration.

I will lay before you the arguments which have been held by some to justify its experimental performance:

1. The prostrate is a sexual gland, the homologue of the uterus.

2. The uterus undergoes atrophy at the menopause, whether occurring naturally or induced by oophorectomy.

The conclusion drawn is, that the prostate would undergo atrophy if the testes were removed.

This argument is somewhat weakened by the fact that the prostate is not, as we have seen, the homologue of the uterus; but, nevertheless, we are justified in thinking that the prostate, a sexual gland, will atrophy with the whole generative system on removal of the master organs, the testicles, just as the whole female generative system atrophies when the ovaries cease to functionate.

To obtain additional light, experiments have been carried out on the lower animals, and these, you will remember, conclusively prove that the normal prostate atrophies after castration in them. This would lead us to expect a similar change in man. But, as I have said, the evidence is not very convincing, and applies almost entirely to eunuchs; and it is manifestly a very different matter that growth should

be arrested than that a fully-developed gland should atrophy. However, quite apart from this evidence, it seems to me exceedingly likely that the normal prostate would atrophy in men if the testes were removed, for it does so in dogs, and there is no reason to suppose its functional position, with regard to the sexual apparatus, different in them to what it is in us.

Granting in this, we are still far from having solved the problem before us; for, although a normal prostate atrophies, it does not necessarily follow that a morbid one will do so. Nor do we know enough about the hypertrophied prostate to say that this is even likely. If we could say that the enlarged prostate was the result of excessive sexual activity the case would be very different; but I am convinced that there is no proof of any kind that such a causal relationship exists. Buxton Browne says he is "more and more struck by the fact that prostatic hypertrophy often follows a second marriage or a marriage contracted early in life." This vague statement is quite worthless. Besides we must bear in mind the important fact, that the hypertrophy occurs, not during the period of greatest sexual activity, but when that function is on the wane.

I would have considered that the argument in favour of castration were not such as to justify its application to men. I would have thought the proper course to pursue would have been to have obtained animals whose prostates had undergone hypertrophy — doubtless, a matter of difficulty—to have castrated them, and, if the results were satisfactory, I would have considered the experiment on man justifiable. Fortunately for surgery, others with better right to an opinion have not considered this intermediate step, with its accompanying delay, necessary; and now the operation has been performed quite a considerable number of times.

The operation was first performed by Ramm, of Christiania, in April, 1893. Since then by Haynes, Professor White, Fremont Smith, and Maunsell Moullin. The results are very satisfactory.

I need only refer in any detail to one case, and I will select the last which I have read of—an operation performed by Maunsell Moullin, in June last, and reported in the *British Medical Journal* of November 3. The patient was eighty-one years old. He had complete retention, due to an enormously enlarged prostate, as felt per rectum. No catheter could be passed, so the bladder was aspirated above the pubes. After this the necessity for some permanent operative relief became urgent, as the man could not sufficiently relieve himself, and he was losing ground. Supra-pubic prostatectomy was out of the question, so the choice only lay between a perineal drainage or castration. Moullin decided on attempting the latter, and performed the operation with the following results:—In ten days the prostate was smaller, and after three weeks all that could be felt per rectum was a fusiform thickening extending along the catheter, so small and soft that the shaft could be felt everywhere through it. An ordinary catheter could be passed with ease.

This result is truly wonderful; and all the other operations performed up to the present appear to have been nearly equally successful.

We may, then, safely conclude that castration can cause an atrophy of a hypertrophied prostate; and, further, that perhaps one would be justified in performing the operation in certain advanced cases as a substitute for perineal drainage. We must remember, however, that, as an operation, it is still in the experimental stage.

This operation of castration brings us to the furthest limit of advance in this branch of surgery, and I will, in a few words, state the conclusions which can, I believe, fairly be drawn from a general review of the subject:

1. Now, as formerly, the large majority of cases require no treatment except regular catheterism.

2. For some, however, this is insufficient, and we may then resort to suprapubic prostatectomy if the patient seems to have sufficient strength.

3. For the very old and feeble there is at present only one operation recognized by surgery—*i.e.*, perineal drainage.

4. But now it seems possible that we may have in double castration an alternative measure. The results already obtained make us hopeful; but I think at present Irish surgery can afford to wait. —*Doublin Jour. of Med. Sci.*

SOME THOUGHTS ON THE METHOD OF RELIEVING AN OBSTRUCTED BOWEL.*

W. THORNLEY STOKER, PRESIDENT R. C. S. I.

It is the privilege of the President of this Section to address the members at its opening meeting on some matter of surgical interest, and it is an occasion when one may fairly be excused if he elects a topic to which he can apply his experience rather than one of the novel and obscure subjects in which the theorist delights to revel, and which capture the intellect rather than deal with every-day incidents of our surgical life.

I do not intend to go far afield for material, because it seems to me that the importance of facts is to be measured by their commonness, and that just as the dignity of labor overshadows the greatness of kings, so the most frequent incidents of our surgical life throw the curiosities and rarities of our science into the shade. Common surgery means universal surgery, and implies that which may be cultivated to the greatest good of the greatest number. What Tennyson has called "the falsehood of extremes" is one that creeps very insidiously into the daily life of the enterprising surgeon. There is a tendency to argue from extreme or rare and individual cases, and to lose sight of broad and collective issues. How often we see elaborate and able papers written with a view to deduce a theory or a practice from a particular and eccentric instance, and the paucity of material concealed by an overshadowing cloud of science condensed from the literature of half a dozen modern languages. This "paper-making" or encyclopædic style is destructive to a fine cultivation of our science, but it is a less evil than that which it conceals—the undue craving after originality. Every second surgeon wants his name connected with an operation or an instrument, and in this age of hot and unwholesome competition the hunger is disastrous to the quiet and perfect digestion of abundant material which waits on normal appetite.

As far as my sight reaches I can see no direction in which the craving for novelty and originality has caused men to overstep themselves more than in the operations undertaken so often and with such a light heart for the relief of some forms of obstruction of the bowel. The hateful expression that "there is practically no danger in opening the peritoneum" is ever before the reader in these days, and, as regards a class of cases I wish to speak of, a more false or poisonous teaching was never promulgated.

It is more than five years since I read before this Section of the Academy a paper "On the Treatment of Acute Intestinal Obstruction due to Collections within the Lumen of the Bowel," and I am here now to repeat with every force I can, and with what added weight time, experience, and the position I now hold, may give to my words, the doctrines I then enunciated.

Do not let anyone misunderstand me—although I hold that we live in a time when there is too free a resort to operation in general, and although we may look for a subsidence of the wave and a return to a normal level—yet I have no cry to raise against the general advance of the operative treatment of the bowel—that would be foolish as well as futile. I have no word to say now against laparotomy in any class of cases save one, and even in that class I make no wholesale condemnation, but only urge that it shall be adopted after grave consideration and in selected instances. My remarks do not apply to obstruction due to neoplasms growing in the substance of the bowel, or to pressure on it by peritoneal or intraperitoneal material; but to those very common cases in which, owing either to an atonic intestine failing in its peristalsis, or a normally strong one becoming overloaded by its contents, the balance between the propulsive power of the bowel and the load it has to move is destroyed. The result is the decreasing power of the gut, its extreme distension, and the production of the condition named *ileus*

* The Presidential Address delivered at the opening of the Surgical Section of the Royal Academy of Medicine in Ireland, Session 1894-95.—The Dublin Journal of Medical Science, February, 1895.

paralyticus. We seldom see these cases until they have arrived at an advanced stage, until great addominal distension has taken place, and until the issue is very evidently one of much gravity.

I have seen a great number of such cases in my own practice and in that of others, and I wish to reiterate the opinion I have already expressed that laparotomy is in them an extremely fatal operation, and should be undertaken only when other legitimate means have been exhausted, or where they are evidently improper owing to the advanced stage or general condition of the case. To formulate rules as to when or in what condition such an operation might be undertaken is not possible except to the book-surgeon. The man who has practical experience knows that abdominal surgery cannot be reduced to a formula, and it is long experience and the tact which may be cultivated, but cannot be conferred, that teach us when we must and may open the abdomen in *ileus paralyticus.* To be sure, even the most skilled may fall into the error of delay, and there is no case so surrounded by doubtful problems as that of which I am speaking.

As regards antecedent treatment I have not much to add to, and nothing to subtract from, what I have already urged in the paper I have quoted.

Of the ordinary local measures, such as the application of heat and rubefacients, I have a growing dread. I have never seen them doing substantial service, and I have repeatedly witnessed their production of such superficial redness and inflammation as served to obscure diagnosis and increase the dangers of operation. If poultices or massage be employed they should be used in such a degree as to soothe or stimulate, but not to produce irritation.

Of the value of belladonna, if used freely and early in the case, I still hold a favorable opinion, and I am convinced that its best therapeutic effect is obtained by administering it if possible uncombined with opium. I have nothing to take from, or add to, the ideas I have already expressed about this drug. Its action is understood, and its administration logical. It relieves pain, while it does its work. It finds its chief use in those cases of peristaltic paralysis due to tympanites or fæcal accumulation, and as these are most often seen in obese persons, and are attended by great meteorism—both conditions which render operation extremely dangerous—this drug is often an alternative with the knife. It should be given in full and repeated doses, and pressed until it shows its constitutional effect by producing either dilated pupil or dryness of the throat. The latter symptom is that most usually seen. It is perfectly useless employing this drug unless it be administered to its full extent. It may generally be combined with calomel. It is remarkable that whereas the tolerance of belladonna when given in chronic obstruction is very variable and its employment requires caution, it is extremely well borne in acute cases. The weak and impeded heart which is present in so many examples of acute obstruction is materially aided by the use of belladonna, which is a most excellent cardiac stimulant.

Of opium itself I still have a respectful terror; it masks symptoms so much that it is capable of being a very destructive agent. Nothing but severe pain indicates its use, and in view of the vomiting which is generally present, it is best employed in the form of morphine, and best administered by the hypodermic method.

Of the early employment of purgatives I am even less afraid than formerly, but I have somewhat modified my opinion as to the best drug to use. While I have not relinquished calomel, I rarely employ it except in combination with belladonna. I have a growing fondness for salines. I generally use the sulphate of sodium, and give it in hourly doses of one or two drams until an ounce or more has been administered. The worst that can result from the use of a cathartic that fails to purge is disturbance of the stomach, and this unhappily is such a usual incident of these cases that it is of less moment than it otherwise would be. The difficulty of giving a purgative is often very great on account of the vomiting which exists, and in such cases their administration by the rectum is occasionally successful. Before using a purgative in this way the rectum should always be washed out with warm water. The greatest therapeutic *desideratum* of our day is a method of catharsis by hypodermic medication; and whoever can discover a purgative capable of this mode of introduction will have done as much for humanity as Jenner or Simpson.

Nothing is more perplexing than the problem of how to purge a patient whose stomach rejects everything that is introduced into it.

Of all the points in the treatment of an overloaded or paralyzed bowel there is none on which my convictions remain stronger, or in which, pleasant to relate, I have seen more improvement in method than in the use of the long enema tube. I have spoken in no uncertain fashion of the uselessness and danger of that instrument called "O'Beirne's tube," all the more awful because it was—and, I fear, still is—the custom to teach that it is safe, and its employment so free from danger that even unskilled persons may use it. Mr. Treves was, perhaps, the first writer to cast discredit on this hoary impostor. It is not enough to recognize its danger unless we also admit its comparative uselessness. Life may be destroyed by it. It is rigid enough to perforate the bowel; and I know cases in which this result has, by a little untrained energy, been achieved. I will undertake to perforate the coats of any average rectum with an ordinary gum elastic long tube, such as is usually supplied by instrument makers; and what can be done may be done, if either enough will or sufficient ignorance be present. So much for its danger; what of its uselessness? I contend that no mechanical effect can be gained by the introduction of fluid into the bowel which is not possible with an instrument 9 or 10 inches long, assisted by the natural penetrating quality of water, by gravitation produced by the posture of the patient, and such gentle pressure as that afforded by the use of a tube to which I shall presently refer. The absurdity of supposing that a pipe can be passed through the sigmoid flexure must be evident to those acquainted with the anatomy of that bowel; and the obvious explanation of the instances where, on external examination, it seems to have been done, can be a difficulty only to the tryo in the dissecting-room or dead-house. The length of mesentery possessed by the sigmoid bowel will often permit it to be pushed into the upper zone of the abdomen by the intrusive instrument. Nor must we overlook the danger of the force with which an injection can be introduced by the powerful pump usually employed with the long tube. I have seen a bowel which had been ruptured with fatal effect by this agency alone. As regards the use of medicaments other than water, and supposed to be solvent—such as oil or oxgall—I disbelieve in their efficacy. They have no effect except whatever moral one they may exercise on the patient or his friends. All that can be done, can be best done by warm water alone.

For some years past I have used but two instruments for giving enemas. One is an ordinary Higginson's syringe, to the nozzle of which a No. 12 or 14 red rubber catheter has been attached. For the daily purposes of the rectal toilet, or in cases where the injection is to be retained, or ejected by natural effort, this will be found perfect. It is absolutely safe, and quite painless. It can be used in the most tender infant or the most callous adult; and in instances where injection is called for in the presence of inflamed piles, it is a blessing without any disguise.

The second instrument is an ordinary red rubber tube ⅛ to ¼ of an inch in diameter, such as is used for washing out the stomach. It is convenient to have circles marked at 3, 6 and 9 inches from its extremity, so as to know what length of it lies in the rectum. A large funnel should fit the dilated extremity and should be transparent, so as to allow the fluid, which is being introduced, to be seen.

The patient lies on his back or left side with the pelvis raised, so as to facilitate the passage of fluid into the sigmoid and descending colon. The only fluid that should be used is warm water, and 8 or 10 gallons of it may be employed at one sitting. The surgeon sits on the right of the patient's bed, introduces the end of the tube, and retains it in position with his left hand, while with his right he holds the other end of the tube, into which the funnel is inserted. The tube is introduced 3, 6 or 9 inches, as may be indicated, and should be occasionally moved up and down in the anus by the left hand. An assistant pours water in the funnel, and the pressure may be varied and adjusted by the height to which it is raised by the operator. The left hand can be used at any moment, when the pressure in the rectum becomes painful, to pinch the tube, and stop the flow. When as much water has been introduced as can be borne, the funnel is removed,

that end of the tube lowered to a basin placed on the floor, and the fluid allowed to run out of the bowel. By repeated operations of this kind large quantities of water may be used, and the bowel emptied without the patient being exhausted by straining or by the necessity of changing his position. The solution of fæces and expulsion of flatus are assisted by the pushing in and out of the tube which I have indicated, and by the varying hydrostatic pressure, caused by alternately raising and lowering the funnel at the free end of the tube.

The advantages of this method over older ones are as follows:

1. The tube is soft and cannot cause injury.
2. The fluid pressure can be regulated to a nicety, and cannot be made excessive; as if undue pressure threatens, regurgitation into the funnel takes place.
3. Enormous quantities of water can be used.
4. The currents created by altering hydrostatic pressure have a powerful solvent effect on the fæces.
5. The operation necessitates no exertion on the part of the patient, no change of position, and can be carried on for a long time without causing exhaustion.

I trust I may be excused for entering into a detail of this kind in the presence of so many accomplished surgeons; but there are many young ears present into which my words may pass. I cannot but [illegible] this apparently simple procedure [illegible] the greatest improvements which [illegible] introduced into the treatment of bowel obstructions. I have avoided many laparotomies by employing it, and I believe have seen a number of lives saved. Like all other surgical practices, it gains value by experience; but I am convinced that those who patiently employ it will esteem it as highly as I do; and I earnestly urge on my younger colleagues the abandonment of the old rigid tube and the adoption of the simple rectal armament included in the two instruments I have spoken of.

It is not alone in cases of fæcal obstruction that this method finds its use. In every instance where it is sought to unload the bowel it will be found of service. It may be used with excellent effect in the paralysis of peritonitis, and will, in that difficult case, produce evacuation where other means have failed.

There is no organ of the body which requires more tender treatment than the bowel, and none which is so often left to be dealt with by the unskilled or uneducated. Many surgeons delegate the use of the enema to an assistant, as if this potent engine were unworthy of their own attention, and many who use it employ undue force. "No force" should be the postulate of our work with the intestine. We cannot be too persuasive, and it is because so much bad practice with regard to the use of the enema is followed, that I have ventured on such an occasion as this to urge my views against the use of a rigid tube, and to plead for one which has both complete safety and infinite advantage in point of merit. I offer you no weary list of cases, because, after all, they are useful only to substantiate opinion, and if you cannot accept a man's deliberate opinion you are not likely to put faith in his cases. Cases can be twisted to prove anything. In such a position as that which, by the kindness of the Fellows of this College, I occupy, a little dogmatism may be excused, and I feel so strongly about this matter of the tube that I have ventured to deal with it in preference to some more brilliant or alluring topic. I beg you to believe that if I speak forcibly it is because I feel conviction, and when I argue for the total abandonment of the older form of tube I desire to assure you that any words I use are spoken with a full recollection of the gravity which my office attaches to them.

Of course the great difficulty to be overcome in acute obstruction is that of diagnosis, and even to the most experienced no finality is possible. There is no branch of surgery in which extended clinical observation and careful reasoning work better together. A simple process of logic will help the most trained clinician to a true conclusion. No cases afford more opportunity for the display of high surgical qualities than those of which I have spoken. Given the proper faculties of observation and deduction, the two qualities which combine to produce great surgical fitness are Thoroughness and Resource, and in the management of obstruction of the bowel there is the most ample opportunity for their development.

THE LIBRARY TABLE.

BOOK REVIEWS.

OBSTETRIC SURGERY. By Egbert H. Grandin, M.D., Obstetric Surgeon to the New York Maternity Hospital, Gynecologist to the French Hospital, etc.; and George W. Jarman, M.D., Obstetric Surgeon to New York Maternity Hospital, Gynecologist to the Cancer Hospital. etc.; with Eighty-five (85) Illustrations in the Text and Fifteen full-page Photographic Plates. Royal Octavo, 220 Pages. Extra Cloth, $2.50, net. Philadelphia: The F. A. Davis Co., Publishers, 1914 and 1916 Cherry Street.

AND

KLINIK DER GEBURTSHULFLICHEN OPERATIONEN, von Heinrich Fritsch, Professor der Geburtshulfe und Gynakologie, Director der Koniglichen Universitats-Frauenklinik zu Bonn, 1894.

Here are two valuable volumes; the first the joint work of two doctors whose names are well-known to the American profession, the other the single work of one of the best of German teachers; each volume devoted to the same subject.

Swift said, "The most accomplished way of using books at present, is two-fold; either, first, to serve them as some men do lords, learn their titles exactly and then boast of their acquaintance; or, secondly, which is indeed the choicer, the profounder and the politer method, to get a thorough insight into the index, by which the whole book is governed and turned like fishes by the tail. For to enter the palace of learning by the great gate, requires an expense of time and form; therefore, men of much haste and little ceremony, are content to get in the back door." . . . "The physician discovers the state of the whole body, by consulting only what comes from behind. Thus men catch knowledge by throwing their wit on the posteriors of a book, as boys do sparrows with flinging salt upon their tails."

Without adopting the superficial method of using books, thus exposed by the satirical Dean, we have thought that a brief, though necessarily imperfect, comparison of these volumes would be useful. The American work has, including the index, 207 pages, and the German 307; the latter too, has rather a larger number of words on a page. The American work presents 84 illustrations, the German 91; the former has several full-page plates, but the German none. So far as the illustrations are concerned, in an artistic point of view the American volume is much the superior. And so far as relates to paper and printing, its superiority is very great.

Both Drs. Grandin and Jarman, and Professor Fritsch dwell at the outset upon asepsis and antisepsis. The former in their joint work lay down rules which we wish every obstetrician would read and remember; many a life would be saved were these rules observed. Here is a passage we must quote, though our space is limited: "If there is one thing more dangerous to the patient than another, it is the vaselin which it is customary to use as an emollient. The vaselin-pot should, once and for all, be banished from the lying-in chamber." Again they say, and we heartily endorse the statement "Creolin will answer as a lubricant for the finger and for the instruments, and this should be the only lubricant allowed in the lying-in room, unless the physician prefers to use sterilized oil." More than once they refer to a solution of creolin: scientific accuracy ought to characterize a scientific book—we have used creolin as an obstetric antiseptic for some years, but we have not seen a solution of it in water. Fritsch commends lysol, and we think from what we have seen, that in Germany it is displacing creolin.

Several pages in the American work are given to pelvic deformities, and in the German a greater number to the mechanism of labor.

In each work the questions as to the application of forceps are well presented. Fritsch refers only to the Nægele instrument, while the American authors mention instruments, especially different varieties of axis-traction forceps, also giving illustrations. Turning is well-presented in each book, only we miss the many illustrations given in the American; the German has not one.

Fritsch presents some subjects not mentioned by the other authors, *e.g.*, cervical hypertrophy, single and double monstrosities, injuries to child in extraction, inversion of uterus, resuscitation in apparent death of the child, etc. On the other hand, much more room is given to some subjects, *e.g.*, symphysiotomy, by the Americans than by the German.

Space does not permit continuing the comparison, and in conclusion we can heartily commend the volume of Grandin and Jarman to the American obstetrician. We might question, for example, the orthography of Beaudolocque, for the first *e* has no right in the name. We might point out also some very careless writing, *e.g.* "The nature of many of the antiseptic agents on which we must needs rely is poisonous to the human body." Would it not be better to say, Many of the antiseptic agents on which we must rely are poisonous? Why should a woman in beginning labor, not be so spoken of, instead of saying she, "is about to perform a physiolgical act? There are many similar faults in the book. But life is short, and the busy doctor, for whom the MEDICAL AND SURGICAL REPORTER especially exists, will not wait for them to be pointed out; he will buy the book, read it, and find in the reading and in its application much good.

P.

DISEASES OF THE EAR. A Text Book for Practitioners and Students of Medicine. By Edward Bradford Dench, Ph.B., M.D., Professor of Diseases of the Ear in the Bellevue Hospital Medical College. Octavo; 645 pages; 8 colored plates and 52 illustrations in the text. New York: D. Appleton & Co. 1894.

In 1891, Dr. B. St. John Roosa published his valuable practical treatise on the Diseases of the Ear, Seventh Edition. Then followed the able work of M'Naughton Jones, and Stewart, of London. In 1893, there was placed before the medical public the translation of the elaborate works of the two great masters in this department, Professors Politzer and Geuber. At the same time there was published in Germany the exhaustive work of Schwartze and Nebant-Schetsch. Now we have the works of Hovell, of London, and Dench, of New York. Mark T. Hovell's smaller book is instructive and practically useful from his long experience in diseases of the throat, nose and pharynx.

The present volume combines all the good points of the most recent works, as well as descriptions of the various manipulative procedures, for the benefit of those not familiar with the subject. In a careful reading of this work one is impressed with the numerous excellent illustrations; with the details of the writer's personal experience, and the care with which he has selected cases for operation. The neglect of this care has been the great cause for which operations on the middle ear have been decried.

In the brief space given for review one may only indicate the chief matters which attract attention. After 72 pages devoted to the anatomy and physiology of the ear, there are four colored plates and 18 wood-cuts, all *very* good. In Chapters III-IV, will be found Physical and Functional Examination. Chapters V-X are given to Diseases of the Auricle. Chapters XI-XVI to Diseases of the External Auditory Meatus, and Foreign Bodies in the Canal, including Exostoses, and Wounds and Injuries of the Membrana Tympani.

Chapters XVII-XXVI to Diseases of the Middle Ear. Instead of middle ear catarrh, the author used the term tubal catarrh, with synonyms of Anti-Salpingitis Eustachian Catarrh, borrowing a term from the gynecologists, but it has the same affection of the Eustachian tube which arises from acute coryza or naso-pharyngitis. Chapters XIX-XXVI to Acute Catarrhal Otitis Media and its complications. Now comes the most important and the best part of the book, the surgery of the Conducting Apparatus, which is most thorough and satisfactory in all the minutest details so necessary to the aural Surgeon. In the concluding chapters will be found Diseases of the Perceptive Mechanism, and Complicating Aural Affections. After a careful examination of the volume, we consider it not only the best work, but also the most practical text book in the English language. L. T.

INEBRITY OR NARCOMANIA. By Norman Kerr, M.D., F.L.S. Third edition, 8 vo., 780 pages. London. H. K. Lewis, publisher.

This book is not in any sense a religious work nor a fanatical sermon on drunkenness, but criticises from every scientific standpoint the misuse of all of the narcotics and of a large number of other drugs not usually placed in this class.

Anyone who has not made special investigation in this branch, will be surprised at the size of the list of drugs which are habitually used by individuals to produce stimulation, sleep, or a pleasant sensation of some sort.

The tendendcy to habitually use these drugs is regarded as a disease, and as such its etiology, pathology and treatment are discussed, and finally the part it plays in jurisprudence.

Having already reached its third edition this book has, of course, a recognized position, but besides being a very instructive medical work, this will prove a very interesting book for any student of human beings and of social conditions. S. M. W.

THE CARE AND FEEDING OF CHILDREN. A catechism for the use of Mothers and Children's nurses. By L. Emmett Holt, M.D., Professor of Diseases of Children in the N. Y. Polyclinic. Attending physician to the Babies' Hospital and the Nursery and Child's Hospital, New York. New York: D. Appleton & Co. 1894. Price, 50 cents.

This is a cloth-bound book of sixty-six pages, arranged in the form of question and answers, and originally intended for the instruction of nurses while in the training school. Some additions have been made, making it equally valuable to the trained nurse, the mother and, indeed, to the average general practitioner. The information is tersely expressed, and the teaching it offers is quite in harmony with the advanced notions of the specialist in children's diseases.

W. H. P.

THE PHYSICIAN'S VISITING LIST for 1895. Forty-fourth year of its publication. P. Blakiston & Co., 1012 Walnut St.

This visiting list—a familiar and valuable friend—comes before us again for 1895, being the forty-fourth year of its publication, which alone proves it has found sufficient favor with physicians. The same general arrangement has been maintained, and the fly-leaves contain many useful tables and data, which often serve one well in emergencies. W. H. P.

Neuralgia.

Dr. Thomas S. Lane, of Bronte, Tex., writes to the *Medical Brief*. that for twenty years he has used, with decided success:

Potassii nitratis	3iv
Aq camphoræ	3j

M. Sig.: One teaspoonful in a half-wineglass of water every fifteen minutes until relieved.

Pills for Chronic Bronchitis.

Ammonii chloridi	gr xv
Ammonii carbonatis	gr xv
Pulv ipecac	gr iii
Morph hydrochloratis	gr i
Mucilaginis acaciæ	q s

Divide into 10 pills, one to be taken night and morning.

—*Medical Press and Circular.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

MEDICAL PRESS.

Dr. Seymour Taylor writes on

Chlorosis.

This affection rarely shows itself in a woman who has borne children, and is most commonly seen in virgins from fourteen to twenty-five years old.

The symptoms are of course well known: pallor, breathlessness on exertion, dyspepsia, constipation, usually scanty menses, etc.

Physical examination usually shows venous humming, a marked systolic murmur in the pulmonary artery, marked tympanitic resonance in one or both flanks, but usually no organic disease of any kind.

Frequently the victims of this disorder are confined to a shop or workroom and therefore cannot take exercise, but occasionally they are the children of wealthy parents, and will then be found indisposed to any avoidable exertion. Constipation is probably present in every case, although unless closely questioned on this subject a patient will usually give misleading answers.

Chlorosis appears to be a severe neurosis which if neglected is apt to terminate in gastric ulcer. That the ulcer is not present at the outset in those cases in which it is found later is shown by the absence of hæmatemesis, although the other classical symptoms are usually to be found.

Subjects of chlorosis are usually found to have a craving for pickles, acids, unripe fruit, etc., and the use of these must be stopped in treatment.

The treatment which gives greatest satisfaction is purgation by any means preferred, but usually by Epsom salts, followed by the use of increasing doses of some of the alkaline iron preparations. Iron, when given without the preliminary purge, is useless.

The dyspepsia usually accompanying this disease is promptly relieved by alkalies, and a favorite combination is that of bicarbonate of soda, aromatic spirits of ammonia, dilute hydrocyanic acid and compound infusion of gentian.

JOURNAL OF NERVOUS AND MENTAL DISEASES.

Dr. R. K. Macalester reports

"A Case of Multiple Neuritis."

An Italian laborer, nineteen years old, had been unsuccessfully treated for rheumatism in the arms and legs for several weeks. When seen he complained of pains in the head, chest, legs and feet; had poor appetite, regular action of the bowels, no lesions of lungs or heart.

The patient could only stand and walk when supported, and then his gait was paretic and the feet were dragged. The eyes were normal, the extensors of the wrist and flexors of the feet were weak and somewhat atrophied, wrist and foot drop present and knee and elbow reflexes absent. The reaction of the extensors of the wrist and flexors of the ankles is feeble to the faradic current, (the only one tried.) An area of delayed sensation was found along the front of each leg. At four weeks after the onset the muscles reacted to a faradic current (though a relatively strong one) the prognosis was favorable and was subsequently confirmed.

The treatment adopted was a single dose of ten grains of calomel, $\frac{1}{32}$ grain strychnine sulphate *t.i.d.* raised subsequently to $\frac{1}{24}$ grain, massage, nourishing food, and the use of the faradic current.

Dr. Charles Henry Brown reports a case of

Infantile Amyotrophic Lateral Sclerosis of the Family Type.

The patient is a boy fifteen years of age, of German parentage, and about whose early history very little information is to be had.

The first symptoms were noticed three years ago and were inability to whistle and to talk plainly. The progress was so rapid that in a week the patient could not without effort move his tongue, whistle nor swallow. Soon there was inability to laugh or entirely close the eyes, and the least exertion caused difficult breathing. The hearing began to deteriorate. Then came inability to button or unbutton the clothes and rapid wasting of the muscles. Twitchings began to be felt in various muscles.

Plates from photographs show that there is lateral atrophy of the tongue and very little power over the organ. All the muscles of the throat and neck are much affected and the diaphragm appears to be also. Respiration is very greatly interfered with. Fibrillary twitchings, exaggerations of the reflexes and retraction of tendons completes the description.

The age and the fact that although the case grew worse until six months ago it then came to a standstill shows that this cannot class as a case of ordinary amyotrophic lateral sclerosis. In other respects the symptoms agree.

Dr. Charles K. Mills and J. W. McConnell report

A Case Indicating the Location of the Naming Centre in the Temporal Lobe.

The patient was a married woman forty years of age, who began to complain of numbness in the back of her neck, with vertigo and an excessive attack of vomiting lasting two days. For three years nothing peculiar was noted, but it was then seen that the patient was acting in an unusual manner. She had been a skilled dressmaker, but now

did inferior work, hung a printed certificate upside down, etc. She woke one morning complaining of hallucinations, acted strangely and toward night had a convulsion attended with unconsciousness. She was now confined to bed for a couple of weeks, seemed to age rapidly, had severe headaches and verbal amnesia. This suddenly increased with a couple of attacks of vertigo. Ophthalmoscopic examination showed the absence of optic neuritis, but there was left lateral homonomous hemianopsia.

There was word blindness without letter blindness. Right sided paralysis without anæsthesia appeared and progressed. Finally death occurred five years after the first symptoms. An autopsy showed a small nodular, partly disintegrated mass about the size of a hickory nut at about the posterior fourth of the third temporal convolution. The surface of the second, third and fourth temporal convolutions in their posterior half were granular and somewhat disintegrated.

A hard, yellowish-brown tumor was found in the temporal lobe mainly in the third and second temporal convolutions, almost entirely in the white matter of the third. Microscopically this was shown to be a glioma, and it almost certainly started in the third temporal convolution at the posterior extremity of the horizontal branch of the fissure of Sylvius.

Dr. F. Savary Pearce reports an

Unusual Case of Locomotor Ataxia.

The patient is a man of fifty-one years who has a good family history, but has had a good deal of care in nursing an invalid wife. About a month ago he rose from his desk apparently in good health, walked to his office door, had a sudden slight vertigo, and developed double vision which persisted.

The second day after this some numbness around the rectum, scrotum, and glans penis was noticed. A few days later weakness about the knees was complained of and a few nights later a sense of darkness before the eyes followed by a sense of heat and quivering about the nape of the neck with great rapidity of pulse heat. Then there began a jerking and quivering of the whole body, and the attack was repeated twice with less severity. Next morning he felt weak and walking on bricks gave the feeling of walking on a carpet, while walking on a carpet felt like soft pillows. This sensation persists. Slight numbness in the extremities developed The only approach to a crisis is an occasional twinge in the lypochondrium and in the calf of the leg.

Besides the sudden onset, and the absence of Argyll Robertson pupil this case is peculiar in that the wife of the man has posterior sclerosis of twenty years standing, which first appeared with diplopia which suddenly left her three months later and that it was one year after the onset in her case, before she had any symptoms of weakness in the legs.

The treatment used for this case is massage, bichloride of mercury, and injections of Brown Sequard's fluid. Some benefit seems to have resulted but the patient has been under the treatment a very short time only. Syphilis seems positively excluded in these cases.

PERISCOPE.

GYNECOLOGY.

Curative Effect of Baths in Diseases of Women.

Dr. F. H. Davenport (Boston *Med. and Surg Jour.*) says:

The treatment by baths plays an important part in gynecology, especially in the class of cases characterized by exudates of the pelvic peritoneum. What is ordinarily meant by the term exudate, may be divided into two parts: (1) the true serous, fibrinous or purulent collections in the pelvic structures; and (2) the peri- and para-metric connective-tissue bands and cicatrices, which must be regarded as the results of the other group. While the treatment of the first class of cases by balneotherapy shows most brilliant results, even an absolute *restitutio ad integrum*, in the case of adhesions and chronic thickenings the effect is merely symptomatic, reducing sensitiveness, relieving pain, and favoring general improvement.

According to Durhrssen (*Centralblatt fur Gynakologie*) these cicatrices do not in themselves cause pain, but favor the establishment of endometritis which is relieved by the baths. To be sure, the endometritis can be ordinarily more easily cured by curetting and cauterization, hence the latter measures should be tried before a course of baths.

Permanent results are not to be expected in cases of (1) retroflexion of the uterus with adhesions, (2) fixation of one or both ovaries by peri-oophoritic bands, (3) collections of pus in tubes or ovaries, as often occurs in connection with gonorrhœal infection. Appropriate treatment of the third class is laparotomy with removal of the diseased organs; of the first and second, forcible separation of the uterine and ovarian adhesions, and consequent increased mobility of the organs under anæsthesia. The movable uterus is then replaced, and (according to Schultze) held by a pessary. Duhrssen, on the contrary, prefers vaginal fixation, and later massage, as advised by Chrobak. The mobility of the

ovary should be maintained by massage after the method of Thure-Brandt.

It is therefore essential, in order to select appropriate cases for treatment by baths, in the first place to establish a correct diagnosis.

The Treatment of Endometritis.

Dr. C. C. Frederick (*American Journal of Obstetrics*), says:

The treatment of inflammation of the uterine mucous membrane is as important as its prevention, and much more difficult. Intra-uterine medication as ordinarily practiced in the physician's office is useless; more frequently it is positively harmful. It is the experience of every gynecologist that many of the cases which come to him with pelvic inflammation give a history of painful intra-uterine medication at their physicians' office extending over a period of months, perhaps, the patient's condition meanwhile steadily getting worse. The dirty uterine sound and intra-uterine medication have caused more serious disease in women than the conditions for which the treatment was given would ever have produced.

In the treatment of these cases we should not forget constitutional conditions which may cause some of the symptoms which we are apt to ascribe to local disease. Tonic treatment will do much for these. I have seen several malarial subjects with profuse uterine catarrh entirely cured by anti-malarial treatment.

True endometritis is best treated by thoroughly dilating the cervical canal, removing the diseased membrane with the sharp curette, and thoroughly disinfecting the cavity, which may then be packed with fodoform gauze to insure good drainage. In spite of all that has been written against dilating the cervix and uterine cavity, provided there be no extensive disease of the uterine appendages the operation is as safe as any in gynecology, if done with thorough antiseptic precautions, with thoroughly disinfected tents. A laminaria or tupelo tent can be rendered aseptic. Endometritis cannot be treated successfully in any of its forms without good dilatation of the cervix as a primary step.

Prevent puerperal infection by practicing antiseptic midwifery; discourage attempted abortions on the part of your patients; have your patients' lacerated cervices and perinei repaired before they lead to diseased conditions; build up your female patients' general health; do very little or no intra uterine medication; cure their endometritis, whether due to gonorrhœa or other causes; correct displacements, if there be no chronic tubal or ovarian trouble or adhesions—and you will prevent much of the pelvic disease for which hundreds of capital operations are done every week.

'Laparotomy for Pelvic Disease. Why Continue it?

The teachings of Lawson Tait in the field of abdominal surgery for disease of the female appendages have, like all improvements of great merit in modern times, been followed by a great deal of good, and at the same time a great deal of evil has followed in the wake of his followers. The adoption of his methods has brought relief to thousands, death to hundreds and the exchange of one misery for another in scores of others. Tait raised modern gynecology to a high plane, but now after more than a decade observation we ought to advance still higher and accomplish more for women than has yet been achieved. Laparotomy for pelvic disease is being done less often now than formerly, the newer procedure being to attack the disease through the vagina, as advocated by Pean in 1891. Other operators have continued the work, and we can no longer resort to laparotomy for pelvic diseases and tumors occupying the pelvic or even the lower abdominal segment. The writer agrees with Jacobs that 85 per cent. of women requiring removal of the appendages have been infected with gonorrhœa, and advocates the total ablation of uterus and appendages when any operation is attempted, claiming that as the disease has infected the uterus it would be worse than useless to remove the appendages and leave the uterus as a source of subsequent infection.

Laparotomy was frequently followed by hernias, fæcal fistulas, returning sutures, etc, But Jocobs states that in not a case of recovery from total extirpation is there a troublesome sequela. Cases amenable to operation through the vagina are fibroids of medium size, small ovarian cysts, large ovarian cysts without adhesions, parovarian cysts. These may be operated upon with or without total extirpation of the uterus. The writer strongly condemns leaving ligatures imbedded in infected tissues which are bound to communicate the infection to the peritoneal cavity, and leaving the infected stumps of infected tubes. He thinks the time has come when the universal custom of opening a women's abdomen by laparotomy for every ailment of her pelvic basin should be abandoned.

In 140 cases of total extirpation by vagina, Jacobs had a mortality of 1.4 per cent. Tait states that a mortality of 3 per cent. is allowable in laparotomy for removal of the appendages. The average time a patient is confined to her bed after a total extirpation is about eight or nine days, while after a laparotomy it is about twenty-one days.—*R. Stanbury Sutton, M.D., N. Y. Med. Jour.*

For Removal of Warts

R. B. Morrison:

Hydrarg bichlor	grs. v.
Acid salicyl	5i.
Collodion	5i.

M.—Apply once a day, removing the crust each time before a fresh application is made. If necessary the mercuric chloride may be increased to 30 grains in the same amount of collodion.

Four applications are usually sufficient for removal by gentle traction; after which dress with simple ointment, as may be necessary.

PHYSIOLOGY.

Physioloy of Intestinal Peristalsis.

Dr. P. Grutzner (*Deutsch. Med. Wochnschrift*), has demonstrated that although as a rule fluids introduced into the rectnm are at once absorbed, in some cases, however, he observed that colored fluids introduced into the rectum of animals could be detected some hours later in other portions of the alimentary canal and especially in the stomach. This led him to a series of experiments, and employing small solid particles he found that they would be transported to the stomach after introduction into the rectum. He observed that if a small quantity of a mixture composed of equal parts of powdered animal charcoal and 0.6 per cent. salt solution were injected into the rectum of an animal, which had been allowed to fast for twenty-four hours before the introduction of the mixture, after the lapse of about four to six hours, the animal being killed, small quantities of the charcoal were present in various parts of the intestine, but particularly in the stomach. In carrying out a similar series of experiments upon the human subject, using starch and table salt for these purposes, G. found that after some hours the starch could be detected present in the contents of the stomach.

The cause of this antiperistaltic movement G. ascribes to the chemical consistency of the fluid with which the particles are mixed, this upward movement invariably taking place when the substances were mixed with a weak solution of table salt, but never when suspended in plain water or other solutions. The table salt seems to act directly upon the mucous membrane of the rectum and occasions this "upward movement," or antiperistalsis. The upward movements take place in spite of the large masses of fæcal matter driven downward, but are confined, however, only to the peripheral portions of the intestinal tract.

Easy and Physiological Method of Keeping Warm.

It simply consists in taking deep inspirations.

The physiological modus operandi, whereby warmth can be afforded to our body when cold by drawing deep, forcible inspirations, taking care, moreover, to hold the air as long as possible before expelling it, is simplicity itself. Muscular action being then directly induced, that of the lungs ensues, alternate pulmonary contraction and expansion obviously acting on the general circulation as a pair of bellows on a sluggish fire, while, moreover, the act of inspiration must necessarily take in more oxygen from the outer atmosphere, and it will again be recalled here that the more thoroughly the blood is oxygenated the more internal heat will be generated thereby.

The author states: "So simple an expedient can be very readily put in practice by any one, and those to whom I have recommended its trial unanimously have described the same results as I have myself experienced when doing so on an exceptionally bitter cold day. Not many exhalations were in any of these cases needed to be taken before a gradual sense of growing warmth, of correspondingly decreasing discomfort, began to assert its presence throughout the person; the internal spasmodic shivering too often felt beneath the protection of the thickest greatcoats gradually faded out of sensation; the ears and nose, but a few minutes previously asserting their retained existence by an almost sore numbness, in their turn would then become comfortably warm after their normal fashion; then, finally, hands and feet which had previously seemed destined to proclaim shoes and gloves as utterly devoid of any protective utility whatsoever, in their turn become permeated with the same satisfactory sense of restored habitual condition of sensibility and warmth."– *T. Brindley James, F. R. C. P.* (*Med. Times & Gaz.*)

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING FEBRUARY 23, 1895.

Captain Henry P. Birmingham, Assistant Surgeon is relieved from duty at Fort Grant, Arizona Territory, and ordered to Fort Trumbull, Conn., for duty relieving Captian Freeman V. Walker, Assistant Surgeon.

Captain Walker on being thus relieved will proceed to Fort Grant, Arizona, and report for duty at that post.

The extension of leave of absence granted 1st Lieutenant Henry C. Fisher, Assistant Surgeon, is further extended one month.

ORIGINAL ARTICLES.

OPERATIVE PROCEDURE FOR THE RELIEF OF PROFOUND DEAFNESS, LOUD SUBJECTIVE NOISES AND VERTIGO.

LAURENCE TURNBULL, M.D., Ph.G., PHILADELPHIA, PA.

In cases of profound deafness with loud subjective noises, not relieved by ordinary methods and accompanied by severe vertigo, one must resort to some operative procedure for relief. We will briefly enumerate the various operations which have been proposed and performed prior to the radical operations of excision of the entire membrana tympani, or of the ossicles, or both, and which in our hands, as also in those others have given the most satisfactory results.

PARACENTESIS OF THE MEMBRANA TYMPANI AND MYRINGODECTOMY.

The operation of puncturing the membrana tympani has been employed since the time of Sir Astley Cooper and is still resorted to for relieving an effusion of serum, pus and blood; also to improve or to reduce a thickened membrana tympani. At one time it was highly lauded and again much neglected; was revived by Bonnafont and others, but never founded upon a true and pathological basis.

The relaxation of the membrana tympani accompanied with thinning of its substance, is a very frequent effect of the protracted presence of mucus within the tympanum, and when mucus is present within the tympanum, the membrane is depressed, at least in parts, rather than protruded outwards. After paracentesis or perforation, it is well to wash out the tympanum with a warm, weak solution of bicarbonate of soda or of chlorate of potash (gr. v to the ounce) which is syringed freely through the perforation. This is done by means of the Eustachian catheter, but in the opposite direction by applying the syringe to the meatus, the nozzle being well covered with elastic tubing so as to fit closely without causing pain. The stream, with care, may be sent up with considerable force provided the Eustachian tube be open, and it will escape by the nostril, the head, of course, being bent forward. This cleansing should be repeated every second or third day until all appearance of an accumulation has ceased. Then a solution of sulphate of zinc (grs. ij–x. ad f. ℥i of water) may be substituted and used in the same way.

When the membrane is incised we often find a yellow viscid matter which should be washed out. In chronic cases it is well to syringe into the tympanum with a solution of the nitrate of silver (grs. ij. v. ad f. ℥j) and then perform inflation.

The author has resorted to this operation in chronic cases of catarrh of the

tympanum, in several instances with more or less success. When it is desirable to make a simple puncture, the instrument Fig. A was employed; but if a portion of the membrana tympani was to be removed

FIG. A.

by excision of a piece of the membrane, or *myringodectomy* with or without cauterization or a large incision made, he used the sickle-shaped myringatome, The operation, in some instances, is attended with considerable pain; to allay this, and the nervous feeling attending the dread of the operation, it is well to employ a 10

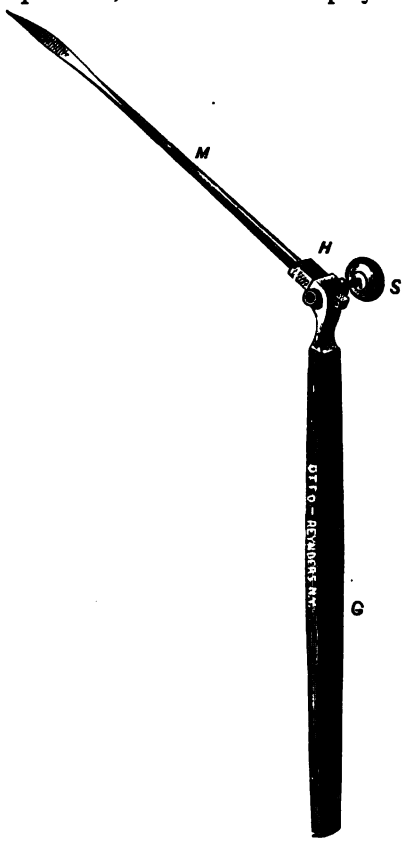

FIG. B.—HARTMANN'S TENOTOME.

Filled in a very convenient handle, it is curved at M and filled in the joint H, while there is a screw at S, so as to hold it firm. Several other instruments can be used in this handle.

grain solution of cocaine. Cauterization of the membrana tympani by the galvano cautery or with concentrated sulphuric acid as recommended by Simcock of New York, only applying one small drop on the point of a glass probe, all the surrounding parts protected.

ACCUMULATION OF SERUM IN THE TYMPANIC CAVITY.

In the valuable monagraph of Politzer on "The Membrana Tympani in Health and Disease," the translators have added a supplement from him of the diagnosis and treatment of the accumulation of fluid resembling serum in the tympanic cavity but not involving the transparency of the membrana tympani; that is it admits light enough into the cavity so that this fluid can be seen, being of a dark gray color on the membrana tympani. The boundary between the parts is marked by a fine black line, having the appearance of a black hair lying upon the membrane. By causing the patient to lie down, the black line changes its position, showing it to be fluid. When the air is forced through the Eustachian tube by Politzer's method and the membrana tympani inspected, the following changes occurred: the lateral portions of the membrane bulged out, and, instead of the distinct limitation in the colors before described, the whole field is covered with rings (or air bubbles in the fluid), of various sizes, having dark contours. The other symptoms were deafness and pressure in the head with loud ringing.

The treatment in the majority of these cases consisted in the employment of his method for inflating the middle-ear, with the head bent over to the opposite side and somewhat forward. In the cases in which the membrane was much shrunken and presented a dark greenish-yellow color, Dr. Politzer, after using the air douche with only temporary success, performed paracentesis and immediately afterwards forced air through the ear by his method, thus driving the matter out into the external meatus.

SECTION OF THE POSTERIOR FOLD OF THE MEMBRANA TYMPANI.

In a small number of these cases has there been permanent improvement. It was first recommended by Politzer in 1871, and a year later by Lucae. His mode of operating is as follows: For section of the posterior fold of the membrana tympani he used a small knife, rounded at its point, sharp-edged, with the blade fixed at an angle to its handle, or else the lancet.

The section is made perpendicular to the longitudinal direction of the fold from above downwards, and the most favorable place for incision is midway between the short process and the peripheral extremity of the fold. The division of the fold is generally accompanied by a grating noise, the margins of the wound recede from one another and the handle of the malleus, which was moved inwards, assumes a more perpendicular position. The bleeding after the operation is generally trifling. Sometimes it is considerable on severing the vascular bundle which extends from the membrana tympani to the upper wall of the meatus, but it can soon be arrested by applying a small plug of absorbent cotton to the incision. This application is also advisable when there is only slight bleeding, to prevent the membrana tympani from being clogged with a crust of blood. Sometimes the blood flows from the wound inwards towards the tympanic cavity, in which case the improvement is observable only after its absorption.

TENOTOMY OF THE TENDON OF THE TENSOR-TYMPANI AND STAPEDIUS MUSCLES.

Improvement in the hearing has at times followed these operations, but now and then there is a decrease of the subjective noises after the operation.

Division of the tendon of the tensor tympani was proposed by Hyrtl in his "Topographische Anatomie," 1847, and was first performed in the living ear by Weber-Liel, in 1868.

The most important objective signs of shortening of this tendon are held to be great inward curvature of the membrana tympani; foreshortening of the handle of the malleus; great projection of the short process and of the posterior fold; and also such a state of the membrane as is often found when the Eustachian tube is impermeable.

The instrument for dividing the tendon of the tensor-tympani is introduced into the tympanic cavity in front of the handle of the malleus by some specialists (Weber-Liel), behind it by others (Voltolini, Schwartze, Hartmann). The latter situation is, according to Politzer, by far the safer and gives the operation a better chance of success.

The tenotome of Hartmann is generally preferred, which consists of a small knife curved on the flat and on the edge, the point of which reaches about 1 mm. farther outwards than its upper edge. This has proved the most serviceable instrument of all, as with it the operation is performed most safely and without any injury to other parts.

To form an accurate estimate of the success of the operation, it is advisable, as was insisted on by Hartmann, first to make an incision into the posterior segment of the membrana tympani about 1 mm. behind the handle of the malleus, and then to ascertain what change occurs in the hearing distance and in the subjective noises. Then Hartmann's tenotome is introduced through the incision into the tympanic cavity for a distance of about 3 mm., whereby the instrument is placed below the tendon of the tensor-tympani between the handle of the malleus and the long crus of the incus. By slightly sinking its handle the sharp point of the tenotome is forced so far towards the upper part of the tympanic cavity that the tendon is obliquely divided when the instrument is withdrawn.

The division of the tendon is often accompanied by a peculiar grating noise, and sometimes a considerable effusion of blood into the tympanic cavity is observed after the instrument has been removed. This is absorbed after a few weeks.

MOBILIZATION AND EXTRACTION OF THE STAPES.

This operation is indicated in very dry middle-ear catarrh, where the function of the auditory nerve is intact and speech may be quite distinctly heard, and to be effective the adhesions must be torn. Simply stretching and pulling them is

very apt to cause shrinking and retraction.

Mobilization of the stapes is believed to give more frequent and more satisfactory results, judging from the first thirty-five cases in which Bucheron has performed the operation. He holds the procedure to be without danger, and comparable on the one hand to the operation for glaucoma—in relieving the pressure on the nerve, and the other hand to that for cataract—in removing an injurious mechanism.

No accident occurred in the thirty-five cases mentioned, except some insignificant cases of otorrhœa, and that in some the chorda tympani was divided with the result of temporary loss of taste in the corresponding half of the tongue.

As a rule the hearing power for ordinary conversation was doubled or trebled. When the deafness was of moderate intensity and duration, there was a very marked amelioration in two-thirds of the cases, and the improvement was immediate.

Boucheron cites two cases as examples, and gives the following indications for the operation if the function of the auditory nerve be unaffected:

1. Certain cases of progressive hereditary deafness, with intermittent obstruction of the Eustachian tube and sclerosing contraction of the ligaments of the ossicles.
2. Certain cases of deafness with vertigo and humming tinnitus (Meniere's symptoms).
3. Certain cases of infantile deafness to mutism.
4. Certain cases of progressive senile deafness.
5. Certain cases of paracusis Willisii.

Extraction of the stapes is an operation which is still under trial, and although very brilliant results have been reported, later observations do not confirm.

SYNECHOTOMY OF THE CRURA OF THE STAPES.

According to Politzer, this operation is only applicable in those cases in which the objective examination gives a marked negation (Rinne), and lengthened duration of perception for the C^2 tuning-fork through the cranial bones, as well as intact tone perception for the acoumeter. Besides, the mobility of the malleus should be proved by means of Siegel's speculum. This operation has been performed in 18 cases. In four of these cases, in which the deafness was of such a high degree that spoken words could be heard only in the immediate neighborhood of the ear, the stapes proved to be anchylosed and the result was *nil.* Of the other fourteen cases, in only five was there marked and permanent improvement in hearing, as the hearing distance increased from 1 to 1½ m.m to 4, to 7.11 m.m. and accompanying subjective noises were decreased. In the other nine cases, the improvement in hearing after the operation was of a slight degree and was transient. The operation is worthy of further trial in properly selected cases.

EXCISION OF THE ENTIRE MEMBRANA TYMPANI AND THE EXTRACTION MALLEUS AND INCUS.

Simrock, of New York, was one of the first who made the experiment of removing the cause of deafness in chronic thickening of the membrana tympani in middle-ear catarrh with adhesions or a partial anchylosis of one or more ossicles. After the operation he found that a membranous cicatrix formed over it, filling the whole cavity and adhering to the inner wall of the tympanic cavity. Kessel advised also the removal of the cartilaginous ring on the posterior circumference of the membrane, so as to obtain a more permanent opening. Schwartze considered it dependent upon the presence of the cartilage at the limbus. It was Dr. Sexton, of New York, who brought the operation fully before the aural surgeons of the world and advocated the operation.

The improvement, as observed by all successful operators, depends upon the stapes, for if this bone is fixed sound conduction is imperfect. This is of the utmost importance to determine before the operation, and this, with other sources of failure, is what has been dwelt upon so much. No reference will be made to the operation of the removal of the whole or of part of the diseased tissue or bones following otitis-media purulenta chronica. This and the consideration of Stacks radical operation for obstinate chronic otorrhœa will be reserved for another paper, having had full opportunity for the study of both classes, and having per-

formed both operations in private and publicly in the clinic with my colleague, Dr. J. MacCuen Smith, in the Ear Department of the Jefferson Medical College Hospital.

A REPORT OF CASES NOT SUITABLE FOR OPERATION AND ILLUSTRATIVE OF THE ABOVE OBSERVATIONS.

CASE I.—*Paralysis of Auditory Nerve.* Martha A., aged forty-nine, living in Chester, Pa., has suffered from deafness for many years, the result of a chronic catarrhal inflammation. Voice not heard unless words were shouted into the ear by a familiar voice, and even then many were not understood, so that she was obliged to resort to writing. No form of ear trumpet improved her condition. The tuning fork was neither heard in the air nor on bones of the head as a musical note. No operation could be performed in this case.

CASE II.—Miss Mary H. C., aged thirty-four; chalky deposit between all the bones with fixation of the stapes. The subject belonged to a gouty family, and was so deaf as only to hear the voice when loudly spoken near the ear and the speaker was looking at her; general conversation not heard. Tuning fork heard when placed over the bones of the head, and in the air when held close to auditory meatus. There was also a family history of deafness. The lady was very desirous of having the operation performed, although no positive opinion of a favorable result was offered. She had been under the care of several competent aurists, but with no permanent good results. Unfortunately, the "Bing" test was not employed. The operation was performed by a friend and a chalky condition was found, only the membrana tympani and malleus could be removed in a broken condition, incus not found. The operation produced a very slight improvement, but with few chances of permanent result. The stapes remained intact, but was more or less involved in the deposit.

CASE III.—Diphtheria; the deafness involving the auditory nerve, etc. R. E. C., aged thirty-six. Deafness in both ears of many years duration, so deaf as to require being spoken to in a very loud tone and close to the auricle.

History: Had a severe attack of diphtheria when a girl, which involved every part of the ears, nose and throat, and her life was despaired of. She recovered her voice and her throat became so she could swallow, but her hearing gradually became more and more impaired, leaving her with sclerosis and atrophic neuritis. In spite of careful treatment of a local and general character, she was unable to hear her own watch in her right ear, and neither voice nor watch in her left. The membrana tympani was very much depressed and filled with cicatricial tissue, and no outline of ossicles could be seen with a bright electric light. Being in despair about her ears, she was recommended to a medical gentleman of this city, who gave her the encouragement that by an operation she would be improved. She was ready "to catch at a straw," especially as the physician told her of successful cases upon whom he had operated. Under an anesthetic, he removed first, the entire membrana tympani and malleus, then the incus, and lastly elevated the oval window to release foot-plate of the stapes. There was unfortunately, not the slightest improvement. Now, this was a case where no operative interference was justifiable except for the relief of a discharge. For several reasons: First, the very profound deafness; second, the deafness being a sequel of diphtheria. This destructive disease not only produces outward changes in the nostrils and throat but almost always involves the tubal muscles with paralysis, followed even by disease of the labyrinth.

THE PROPER CLASS OF CASES TO BE OPERATED UPON—THE PROPER METHOD OF OPERATING, AND THE RESULT OF THE OPERATION UP TO THIS TIME.

Healthy family history, of which we have already spoken; no hereditary tendency to deafness; ability to hear the voice as speech, even when spoken close to the ear; no ozena or atrophic rhinitis; ability to hear the voice through the hearing trumpet or according to the "Bing" method, as speech.

It is an absolute rule first to be certain that the auditory nerve is not organically diseased but only functionally involved, by careful testing. For if a patient is unable to hear the combinations of letters and words in speech loudly spoken in the

ear, the case is not a suitable subject for operation. If the patient is unable to hear the lingual R, it is often an indication of defects of the membrana tympani. Care should be taken that the mouth is not seen nor the lips read when making these examinations.

Still another test is by means of the speaking tube or trumpet, for "if speech is not heard through sound conduction by means of the ossicles, hearing does not exist" (Politzer). Each ear should be examined separately, and the testing performed as follows: The patient stands opposite the physician, facing him and with his eyes directed downward to the flood. The patient is tested first by means of the self-sounding consonants alone, R lingual, B, K, T, F, S, Sch, G soft, as well as the very deeply whispered U. Being unable to hear the F sounds occurs oftenest in labyrinth disease, according to Wolf. Politzer holds that his method of testing the hearing distance for speech, before and after treatment, is the most important, as it gives the surest judgment of the amount of and the improvement in hearing. It is also necessary to determine whether or no there is anchylosis of the stapes, for the malleus and incus may be removed without the slightest relief to the deafness as the stapes is fixed in the bone (oval window).

Dr. Bing, of Vienna, has by this method, been able to assist us in making a diagnosis concerning the variety of deafness before operating. He calls it the "entotic" use of the speaking tube—speaking into the funnel of a speaking tube while in position, the other end of which is directly connected with the cavity of the tympanum by means of fitting into a catheter introduced in the Eustachian tube. By this means the waves of sound pass through the speaking tube, catheter and Eustachian tube into the cavum tympani; they reach the foot-plate of the stapes and the fenestra ovalis, and by them communicate to the fluid of the labyrinth and auditory nerve.

According to Politzer, in a case where speech is not heard through a speaking tube in the external meatus by the "entotic" method, there is a hindrance to sound conduction in the malleus or incus and the foot-plate of the stapes is not freely movable in the fenestra ovalis.

In another article we will give the proper method of operating, and some of the collected results of the operation.

GUNSHOT WOUNDS.*

GEO. R. DEAN, M.D., SPARTANBURG, S. C.

The literature of gunshot wounds in private practice is very meagre, and he who depends upon it for guidance in emergencies will be greatly disappointed.

The safest and only fixed rule here, is a sound surgical knowledge, based upon known truths of pathology, and brightened by a cultivated and continuous study of the latest developments in surgical proceedings. For there can be no absolute ironclad rules laid down from which, in such cases, one can choose that which is suitable to his own use, but must depend upon his own surgical skill and knowledge to adapt his treatment to the case in hand.

In the South, where gunshot wounds are prevalent as a mode of personal injury, we ought to have more knowledge of the history, treatment and results of such injuries than we now possess.

But to my surprise, I find the data even here very scant. I do not propose in this paper to seek out and record the cases reported and the results obtained by others, but will try to interest this Association with some cases, and will deduce some facts from them that may hereafter be of service to others.

GUNSHOT WOUNDS OF THE ANKLE JOINT.

CASE I, of A.—A lad of fourteen years, while toying with a pistol, accidentally discharged it, the ball entering two inches above the internal malleolus of the right leg, passing down and outward, pene-

* Read by title before the South Carolina State Association, 1894.

trated the lower end of the tibia, and on through the ankle joint and into the os calcis, or into the articulation between it and the tibia, and lodged somewhere in that vincinty.

It was a 38-calibre, Smith & Wesson pistol, and of great penetrating power. It passed through about two inches of bone in all. I saw him about two hours later, gave ether, and tried to find the ball, as I thought it would probably disable the boy if left where it lodged. I could find nothing but pieces of shattered bone. I washed out the wound with bichloride 1:2000, and sent him home, promising nothing as to prognosis.

The next day, temperature 100°, otherwise doing well; kept up the bichloride wash twice a day, temperature rising gradually for several days, never, however, rising above 102°; usually rested well, with phenacetine at night. In six days suppuration had set in, much to my regret.

This kept up for several days, when I discovered a flushed and tender spot below the internal malleolus. This I afterwards opened, and it discharged freely. I now gave up all hope of saving the joint as a useful appendage. Four days after this another abscess came on the malleolus, and broke before I saw it. Now the cause for the suppuration I had labored so hard to prevent was made manifest. Something dark appearing in the opening, I picked it up with forcep, and extracted a piece of woolen sock carried in with the ball. This was repeated from day to day until all was out. After this all the places, together with the wound of entrance, healed up kindly, and the boy soon took up his crutches, and at this time, four months since the accident, walks half a mile to school, with a slight deformity in his gait, and with a moderate degree of impairment of the usefulness of the joint itself.

Since this was written the ball appeared just under the skin, to the right of Tendo Achilles, above the os calcis, and was cut out by the father of the boy. The lameness is greatly improved.

GUNSHOT WOUND IN THE KNEE-JOINT.

The second case appeared in the practice of my friend, Dr. H. A constable fired a No. 38 ball, from a Smith & Wesson pistol, into a fleeing prisoner, the ball entering from behind, in the popliteal region, passed around or through the knee-joint, and when he was seen by Dr. H. the ball could be felt in front, near the patella. He was kept quiet with an antiseptic dressing over the wound, and a splint and roller over the leg and thigh for several weeks. The splint was removed and the leg left free, only he was not allowed to move it about. We saw him together frequently, and found the ball floating about in the accumulation of fluid that had gathered and could be pushed from front to rear around the joint, or through it and under the patella. In fact it seemed to be a privileged character in the joint, going when and where and how it pleased. After consultation, some days afterward, we decided to open the joint and extract the ball. This we did by pushing it down to its lowest descent, gathering it between the fingers, incising the skin upon it, and sewing it up, dressing antiseptically and placing the leg again at rest. It healed kindly and the man made a perfect recovery, with perfect use of the limb.

CASE III. J. B.—A constable in attempting to arrest a man became engaged in a fight in which the man was killed and J. B. desperately wounded.

The wound was made with shot about No. 4, and was fired from left and rear and not very far distant. The load entered the back four and a half inches to the right of the spinal column, and over the region of the eleventh and twelfth ribs. After being shot he walked half a mile to the county jail, and from there was conveyed to his boarding-house, half a mile distant. I was called at once to see him, but being absent Dr. L. K. Blake saw him for me and was engaged with me in the case until convalescence. B. is a man of powerful physique, over six feet high, weighing two hundred and forty pounds, aged forty, a man inured to labor and hardships, a carpenter by trade. When wounded he was on the state constable force in the discharge of his duty. When first seen by Dr. Blake, one hour after being wounded, there was much pain in the region of the liver and lower portion of right lung. Morphine and whiskey was given, wound dressed and he was made comfortable. I saw him at three o'clock the following morning

and found the following conditions: Wound as above described. The load seemed to have entered at an angle of about 30°. There was one central ragged wound large enough to admit the ends of three fingers and around this numerous shot holes, variously grouped, some ranging deeply into the tissues, others following the direction of the ribs just beneath the outer surface. The appearance of the outer wound seemed as if most of the shot had taken the latter direction. We did but little probing, as we did not wish to add to the traumatism already existing. After consultation with Drs. Heinitsh and Blake it was decided to treat his case expectantly, as it was believed that the liver and colon were seriously damaged. The pain in the liver and difficult breathing, together with the location of the wound, and the great thickness of the abdominal wall led us to this decision, believing that in a few days he would probably die, and that operative interference would only hasten the end. So from day to day we watched him, and thought we could see the end approaching closer and closer. Of the ten physicians who saw him about this time all said he would die. We will now take up his history during this trying period and see what was the outcome.

NOTES ON BLAYTON'S WOUNDS.

December 27th, 9 P.M.—Some shock and chill, great restlessness and pain over right lung, in front about the sixth and eighth rib, pulse 76.

December 28th 3 A.M.—Pulse 96, resting quietly under morphine.

9 A.M.—Temperature 100°, pulse 100.

4 P.M.—Temperature 102°, pulse 106, vomited.

9 P.M.—Temperature 100°, pulse 106, vomited freely.

December 29th, 8 A.M.—Pulse 106, intermittent and very irregular, vomiting continuously, countenance anxious, temperature 98; bowels moved to day.

4 P.M.—Pulse 120, temperature normal, vomits only when taking whiskey; retains milk well.

8.30 P.M.—Temperature 100 2-5°, pulse 108, conditions somewhat better.

December 30th.—Pulse 104, temperature 99°, no vomiting, retains milk well.

2 P.M.—Pulse 100 and good temperature, 97½°. Gave morphine, rested comfortably except for great distention of abdomen.

6 P.M.—Temperature 97 2-5°, pulse 164, sank rapidly to 180 in half an hour; gave nitro-glycerine and digitalis; Cheyenstokes respiration.

8.30 P.M.—Temperature 97 2-5°, pulse 180, weaker, strychnia and morphine.

9.30 P. M.—Pulse 132, temperature 99 3-10°.

December 31st, 3 A.M.—Pulse 120, temperature 97½°. 7 A.M.—pulse 168, temperature 97 4-5°. Gave strychnine 1-20 gr., morphia ½. Great abdominal distension. 10 A.M.—pulse 160. 10.30 A.M.—pulse 168. Gave strychnine $\frac{1}{10}$ of gr. 2.45 P.M.—pulse 118; complaims of pain; strychnine and morphine. 3.35 P.M.—pulse 180. At 5.45 P.M.—pulse 200; gave strychnine, 1-30th of a grain. At 6 P.M.—pulse 188, temperature 97½°; his condition extremely unpromising and death expected every hour. At 9.45 P.M.—pulse 180, temperature 97 2-5; nitro glycerine, strychnine and morphine, great abdominal distention, heart irregular, and varying as much as 60 to 80 beats to the minute within space of half hour; first signs of mental abberation; retains milk and soft boiled egg. 12 P. M.—pulse 200, feet and legs cold to the knees, sleeping well. January 1, 1891, 1 in the morning—pulse 180, strch. and morph. 3 in the morning—pulse 160, temperature 89°. 9 A. M.—pulse 176. At 8 this morning a sloughing of the wound opened into the cavity, exhaling therefrom a fecal odor, mixed with other foul gases, discharged a large amount of blood, serum and pus. 10.30—pulse 172, a free discharge from wound. 4 P. M.—pulse 160, wound discharging freely.

January 2d, 7 in the morning—pulse 108. 11 A. M.—pulse from 60 to 100, temperature 98°; wound discharging less, condition improved. 3 P. M.—pulse 120, chill, temperature 99½°, restless and anxious, morphine. 9 P. M.—pulse 120, resting under morph., bowels moved with anema. January 3d, 8.30 in the morning—pulse 142, wound discharging more freely, decided fecal odor, bowels moved first time voluntarily. 10.30—wound dressed, followed by chill, with great restlessness and anxiety.

12.30 P. M.—pulse 212, pupils dilated, active delirium gave half grain morphine. (Suspected here an overdose of atropia

given by the nurse by mistake). 5 P. M. —pulse unsteady at 80, two beats with intervals, breathing 20 and labored.

January 14th, 8 in the morning, rested well last night, two stools during the night, pulse 72, temperature normal. 9 in the morning, pulse 72, temperature normal, less discharge from wound, conditions better. 9.30 P. M.—passed a good day, bowels soft and free from pain, temperature normal.

January 5th. Memoranda lost, but nothing unusual to-day.

January 6th. 9 A.M.—pulse 90 and good, slight cough, compound spirits ammonia prescribed, two stools, cheerful and bright. 8 P. M.—About the same, slight static pneumonia, discharge from wound less offensive, wants to eat, sat propped up in bed, large fecal discharge to-day, consistent, marked on one side with bloody mucous.

January 7th. Condition fairly good.

January 8th. Condition same, profuse sweat the night before.

January 9th. Condition same, removed paper wadding and necrossed tissue.

January 10th. About the same, a portion of two ribs exposed to view devoid of periostium.

January 11th. Wound discharging very freely. 7. P. M.—Temperature 100°, pulse 108, seems not so well.

January 12th. 9 A. M.—Rested badly, temperature and pulse improved, sweated freely. 8 P. M.—Sweating during the day, no fecal odor from wound, temperature and pulse good, sloughing about over, with strong light can see into the abdominal cavity, wound looks better.

January 13th, 9 o'clock in the morning, looks and feels well, can see large intestine through opening in abdominal wall, can detect one shot hole in the colon. 6 P. M.—Pulse 108, temperature 101°, restless and anxious, gave strychnine.

January 14th. Pulse 124, temperature 102⅘°, at 9 o'clock in the morning, bad night, no sleep, no appetite, small hole apparently in mæso colon, discharging pus. 11 in morning recalled to patient, temperature 103⅘°, pulse 144, chill at 10.30, rochelle salts and strychnine.

January 15th. 9 in morning, condition improved. 1.30 P. M.—Temperature 101°, pulse 108, seems better, enema of warm water passed out readily through the wound, morphine and strychnine. 6.30 P. M.—Temperature 101°, pulse 100, copious discharge from bowel. 9.30 P. M. —Sleeping soundly and breathing quietly.

January 16th, 17th, 18th and 19th. A gradual improvement, wound filling up slowly. 20th and 21st.—Periosteum beginning to cover exposed ribs, photographed wound to-day, temperature and pulse normal. From this time on improvement was gradual, but progressive, and on the fifty-first day he was discharged.

In the above notes only the more salient points of the treatment have been given, as a minute detail would become tedious. Each symptom was met as it appeared, and treated as indications demanded, keeping ever in view the fact that no set rules, but sound, surgical knowledge should be our guide in such conditions.

This was a more fortunate termination than could at any time during the first ten days have been hoped for. The man, first of all, had an iron constitution, capaable of great resistance to depression, and he had hope even in his darkest hour, of ultimate recovery. The turning point, however, upon which his recovery hinged, was reached upon the day when his wound had sloughed sufficiently to permit discharges to pass through.

His condition from this time improved, and although relapses occurred, they were only temporary and soon passed away. This, then, brings me to a point the gist of which is drainage.

I was not misled in this case, however. We had talked of this and had discussed the propriety of opening the abdomen early, but believing the traumatism to liver, bowels, etc., to be so great that any interference would hasten dissolution, we preferred to wait. Had the wound been in the abdomen, away from the ribs, and out of probable reach of the liver, I should have urged the opening of the abdomen the first day, draining, if nothing else. True, this man recovered without surgical interference; nevertheless I think in all cases of wounds of the abdomen, where the cavity is penetrated, it should be opened and explored, intestinal wounds repaired and the cavity thoroughly washed out and drained. This is a position that nearly all advanced surgeons maintain. This case only serves to add that much more proof to the argument.

Since the introduction of the Murphy button, repairs can be quickly made in the bowel. The object of this paper will not permit a minute description of the toilet and surgical procedures in such cases, but I will say this much, that a surgeon who will let a man who is injured in the abdominal viscera die without opening the cavity, provided he sees him when not in collapse, and washing it out, repairing damages and draining, is remiss in his duty. We should not wait for alarming symptoms to appear, for when they come, the patient usually goes. Quick, clean work, small incision, even left unclosed if necessary, to save the patient from collapse, and ample drainage will often save life. In this case I do not think I did the best think for my patient by waiting, although he pulled through without operations. I think now a drainage tube in his abdomen the second day would have saved him much suffering and risk to his life. Had I known at first that the liver was uninjured, I would have opened the abdomen the second day. The time that has elapsed before a patient is seen where the cavity of the abdomen has been penetrated has much to do in the prognosis of an operation. After 24 or 36 hours have elapsed, peritonitis or sepsis may, and generally have supervened if the bowel has been penetrated. An operation after these had set in is not so hopeful of good results as before such conditions have taken place. Hence, the earlier the case is seen the greater the possibility of good results from operation. There is more time at the disposal of the surgeon, and he can make a more careful and intelligent search for wounds of the viscera, with less liability of shock and collapse. When these conditions exist, an operation should not be denied; but here it should be limited to the real necessity of the case, and no attempt at ideal surgery made.

The abdomen should be opened quickly, under cocaine, if great weakness is present, and flushing with hot water, drainage, even without stitching the incision if necessary simply closing it with bandages and dressing, putting patient to bed and trying to save his life.

Life here is at stake, and everything should be held in abeyance to that one idea. Insufflation is not to be relied upon here, only in so far as it may aid in discovering the perforations in the bowel, after the incision has been made, and during the operation to prove the integrity of the bowel. Even here the great distention produced in the bowel will often be a source of great inconvenience.

The cases shot in the knee joints and ankle were remarkable in that neither joint was greatly injured, one scarcely any, and the other so slight that it can hardly be detected. Pistol and rifle balls are more or less disinfected by the heat from the discharge, and possibly from their rapid flight in the air, and will often remain in the tissues harmless for years. From this fact I do not deem it prudent in injuries of this character to be zealous to find the ball and extract it. More injury is sometimes done by the probe and forceps than by the ball itself. The wound should be carefully and gently examined and all filth, dirt and clothing removed from in or around it. This can be done without great pain or inconvenience to the patient, and dressed antiseptically. Agnew recommends immediate search and extraction of the ball, if possible. This under some conditions is correct and is good surgery, but not under all is it advisable. Where a large ball from a larger pistol or rifle enters a portion of the body at such place as can be reached the traumatism is so great that it may be best at once to seek the ball at the risk of much pain and inconvenience to the patient. A large ball usually carrying so much material with it, such as clothing etc., that it is almost impossible to have the wound heal without suppuration.

With smaller balls it is different. The wounds often heal without any trouble.

Of course good sense and judgment must often govern us in practice under varying circumstances. Shock must be considered, and the organ or portion of body affected will have much to do with the results of interference. I have often seen wounds made by small balls heal with scarcely any inflammation, giving no trouble afterwards, or later the ball attaining a position from which it can be easily removed. The history of these three cases demonstrates the fact that all such wounds need not be probed nor the ball extracted from them to save life or limb. Where the ball can be removed without violence or danger to the patient it should be done, otherwise it should be left to nature and antiseptic treatment.

ANEURISM OF THE ARCH OF THE AORTA.

R. M. WIGGINTON, M.D., WAUKESHA, WIS.

Frank M., aged about forty; American birth, Irish parentage; nervo-bilious temperament; not robust health; weight 140 lbs.; a dining-car conductor.

This gentleman came to me for treatment June 30, 1893, complaining of easy exhaustion upon exercise, slight difficulty in breathing and some pain and aching in the apex of chest, more particularly upon the right side. He was quite nervous, with an expression of alarm in his countenance.

Upon examination I found the valvular mechanism of the heart apparently a-right.

An impulse of the chest wall could be distinctly felt to the right of the manubrium of the sternum, especially within the intercostal spaces of the second, third and fourth ribs.

Upon auscultation, a distinct murmur *souffle* could be heard over that part of the chest wall giving the greatest impulse to the hand. This sound corresponded with the systolic movement of the heart and resembled very much the diastolic, regurgitant murmur in disease of the aortic valves.

I told the patient that I suspected aneurism of the arch of the aorta, and directed treatment accordingly, which, in brief, was quietude, regard to diet, care of the stomach and bowels; and as medicine, ergot and iodide of potassium.

Under this treatment he soon began to improve, and on July 22d he came to my office feeling, as he said, quite well.

However, upon examination, I told him he was not well, and warned him against all excitement and labor, and not to return again to work until he saw me. Contrary, however, to my advice, he almost immediately resumed his work again as conductor on his dining-car. I did not see or hear from him again until September 6th, when I was called to visit him in Chicago. I found him at the Baptist Hospital. He was very much prostrated, and the disease, which was unmistakably aneurism of the arch of the aorta, was advancing rapidly. The tumor was rapidly growing and protruding itself through the second and third intercostal spaces, and was very evident to both the eye and the touch.

Owing to his great desire to die at home, he was placed in an easy riding-car and brought home to Waukesha a few days after my visit. He rapidly went through all the phenomena common to this form of aneurism, finally dying October 11th from suffocation from the pressure of the tumor upon the trachea and apex of the lung and larger bronchi.

Post-Mortem Examination.

Fully two-thirds of the right cavity of the chest was filled with the tumor, the right lung having nearly disappeared through pressure and absorption. The aneurism was of somewhat irregular shape, conforming largely to the chest walls; in fact, the walls of the chest, the heart and the remnant of the right lung, together with the convex or upper surface of the diaphragm, constituted the boundary walls of the tumor, the crescentic layers being in part bound fast and intimately blended with the pleura, and could not be dissected off. The aneurism contained within its cavity about a quart of semi-clotted blood; and the walls, composed of crescentic layers, were in many places from one to two inches thick and firmly organized.

The aneurism had gradually burrowed through the walls of the chest, destroying the soft parts, the sternal ends of the clavicle, first second and third ribs, and a portion of the sternum, upon the right side, leaving the sharp ends of these bones sticking well into the isthmus of the tumor, which again spread out over the chest beneath the muscles and integument, like a large flattened orange.

The aneurism seems to have originated at the second segment of the arch.

I make this report simply for its statistical value.

COMMUNICATIONS.

A CLINICAL STUDY OF THREE CASES OF SPONTANEOUS HÆMOPHILIA IN BROTHERS.*

JUDSON DALAND, M.D.,† AND W. DUFFIELD ROBINSON, M.D., PHILADELPHIA.

The occurrence of three cases of hæmophilia in one generation, with the tendency so marked that in two of the brothers there was a fatal termination, justifies the addition of this report to the literature on the subject.

CASE I.—Boy, aged thirteen, living in Pennsylvania, at an elevation of 1800 feet. He was born at full term, and there was nothing unusual or remarkable during pregnancy or delivery, nor was there unusual bleeding. For eight months he was healthy and vigorous, and the skin was exceedingly clear, transparent and pale. At that time he was taken with cholera infantum, and was ill three months. His recovery was coincident with the first frost that occurred that year, to which climatic condition his physician ascribed his recovery.

As his mother was unable to supply nourishment he was fed by the bottle. During the last two weeks of his illness there was noticed a profuse petechial eruption over the abdomen, the back and the legs, and, to a less extent, over the arms. The eruption was described as rounded, non-elevated spots of the size of a pin-head, black in color, uninfluenced by pressure, evidently purpuric in character. There was no hemorrhage from any of the mucous membranes.

After this illness he remained well until about the age of five years, when he suffered from an attack of arthritis, affecting especially the elbows, knees and wrists, and this was accompanied by fever and acid sweats. The joints were swollen, red and painful. Relief was apparently obtained by the use of moist applications and the internal administration of salicylic acid and salicylate of sodium. From the fifth year up to the present, the thirteenth year, he has averaged one attack of arthritis every two months, and the peculiarity of these attacks, which usually followed exposure to cold or wet, was that the symptoms appeared forty-eight hours after the exposure. Recently the attacks have been less frequent and less severe. Soon after the fifth year the arthritis was so severe that considerable ankylosis ensued, necessitating the use of crutches until the ninth year, when relief was obtained from Swedish movements and massage. At the age of eight he had an attack of measles, whooping cough and scarlatina, from which he recovered without any complications or sequelæ. Since the age of five he had, approximately, *fifty* attacks of hemorrhages from various mucous membranes, but there was no recurrence of purpura. His father has observed that prior to the hemorrhages there would be grinding of the teeth or the face would become flushed, and in consequence he was frequently able to foretell an attack. Most of the hemorrhages were nasal, but on two occasions hæmatura followed trauma of the renal region, and on one occasion hæmatamesis, from the same cause, applied to the abdomen. Later he accidentally bit his tongue, which was followed by oozing, and then free hemorrhage, which continued for seven days. To control the nasal hemorrhage many remedies were employed, but relief was only obtained when ice was applied to the nape of the neck and to the bridge of the nose, *after* large quantities of blood had been lost and when the physician in attendance thought death was imminent. For the injury to the tongue Monsell's solution was first used, which caused a cessation of the bleeding for a short time; but soon the coagulum was loosened by the oozing of blood of saliva, so that the hemorrhage was more violent than at the first, owing

*Read before the Philadelphia County Medical Society January 9, 1895.

†Lecturer on Physical Diagnosis and Instructor in Clinical Medicine in the University of Pennsylvania; Assistant Physician to the University Hospital; Fellow of the College of Physicians, Philadelphia.

to the destruction of the tissue produced by the remedy.

Effort to check the hemorrhage from the use of intense cold produced by an ether spray proved valueless, as the spray could not be continued for a sufficient length of time, owing to the danger of ether narcosis and the repeated attacks of vomiting excited by the anæsthetic.

Compression by means of forceps was attempted, but owing to the site of the injury, which was on the side of the tongue, about two inches from the tip, it was extremely difficult to properly apply the forceps for any length of time without exciting gagging and vomiting.

Ice was applied for five minutes, until the wound was partially frozen; then it was removed for a similar time, and subsequently reapplied. This was continued for twelve hours, after which the hemorrhage ceased. At that time he showed all the evidence of extreme anæmia and caused his physician to think that death was imminent. Fluid extract of ergot was given in thirty drop doses every three hours.

After each of the hemorrhagic attacks there was nausea and vomiting. When the finger was cut it bled continuously for hours, and was only relieved when Monsell's powder was applied. His father distinctly recalls a number of occasions when this boy received a slight blow on some part of the body, so slight as not to produce even a bruise in a normal individual, which was followed by great pain, swelling, fever, and discoloration of the skin, showing that a considerable extravasation of blood had occurred. The greatest swelling was observed forty-eight hours after the reception of an injury, at which time the pain disappeared. The slow development of this swelling and discoloration of the skin would seem to prove that the more deeply-seated blood vessels were ruptured, from which oozing took place. The slight traumatism was able to produce this result owing to the extreme vulnerability of the walls of the blood vessels.

The patient has been always intensely nervous and sensitive, and frequently, after suffering from an attack of so-called articular rheumatism, he complained bitterly of pain in the joints from the vibration produced by anyone walking about the room, even though his parents were unable to detect any movement of the bed which he occupied.

A week ago, while visiting Philadelphia to receive massage for partially ankylosed joints he was observed to be extremely nervous, with choreiform twitching of the muscles of the face. That night there was grinding of the teeth, and the left edge of the tongue was bitten about half an inch from the tip, produced during sleep by the grinding of the teeth or from a slight convulsion. The following day there was a slight oozing, which continued for seventy-two hours, and increased until he lost about one ounce of blood per hour.

Many local remedies were tried, among which may be mentioned the use of powdered alum, antipyrine, Monsell's solution, and ice, but all proved valueless. Large doses of the compound syrup of the iodobromate of calcium were administered, and also ergot, oil of erigeron, and gallic acid; but these remedies were inefficient. On the sixth day of the hemorrhage I was given an opportunity of studying the case with his attending physician, Dr. W. Duffield Robinson. I found the patient to be well developed, his skin and mucous membranes were pale, the pulse frequent, feeble, and regular. The heart was slightly dislocated toward the right, the apex beat could be felt in the sixth interspace, but occupied a somewhat larger area than normal; the first sound was weak and the second sound sharp and accentuated. No murmur at the apex was audible, although a systemic murmur had been detected by Dr. Robinson at a previous examination. Over the aortic cartilage a sharp second sound was heard, and the pulmonic second was also sharp. Despite the high grade of anæmia present no hæmic or other murmur was audible. The examination of the lungs and abdominal viscera was negative. The skin was carefully examined, but only one purpuric spot was detected, on the inner surface of the left knee-joint, occupying an area having a diameter of three-fourths of an inch. It was supposed that this was due to a slight injury, as no other subcutaneous effusion of blood occurred. The right leg was slightly shorter than the other, and the left knee-joint was considerably enlarged. The muscles of the legs were moderately atrophied. The physiognomy showed that the patient was intellectual, bright, precocious, and the skull was capacious.

As several acts of vomiting had oc-

curred, and nausea and intense thirst were complained of, the administration of food and remedies by the mouth was suspended, and a nutritive enemata given, to which fluid extract of ergot was added. To secure relief from nervous and muscular excitement, and to insure quiet, large doses of paregoric were given per rectum, with 15 grains of trional to secure sleep. On the seventh day, from 6 A.M. till noon, the father, who had observed him continuously, reported that the amount of blood was trifling and that very little had been swallowed. During this time ice had been applied every alternate five minutes. His condition showed that a considerable quantity of blood had been lost during the previous twenty-four hours. It was observed that the pulse at the wrist numbered 70, while the heart-beats were 130 per minute.

Physical examination showed that the arterial system was partially empty and the veins collapsed. It was evident that the peripheral circulation was imperfect, as not more than half of the systoles of the heart were able to produce a pulse at the wrist. This condition of the peripheral circulation, the increase in the amount of fibrin that occurs after large hemorrhage, together with the muscular and mental quiet produced by opium, were counted to favor the formation of a coagulum, thus checking the hemorrhage. A minimum quantity of water was allowed, despite severe thirst, so as to prevent refilling of the almost emptied vessels with the concurrent increase of blood pressure and danger of expelling a slow-forming clot. An examination of the blood showed that it was rather lighter in color than normal, liquid, and, notwithstanding the large quantities lost there was but little tendency to the formation of clots. This want of coagulability was and always has been a marked characteristic of each of these hemorrhages.

Microscopic examination of the blood showed an enormous number of very small microcytes, many of which were mere points. There were a few macrocytes and a moderate increase in the number of leucocytes. There were no parasites nor distorted red blood-cells, and crenation and rouleauxing were normal. The blood for this examination, which was obtained at the end of a protracted bleeding spell extending over a week, showed a decidedly greater tendency to clot than on any former occasion.

The Thoma-Zeiss hæmocytometer showed 3,775,000 or 75.5 per cent, and Fleishl's hæmometer showed 62 per cent. of hæmoglobin.

The next day an examination showed well-marked evidence of quantitative and qualitative anæmia, no hæmic murmurs audible, although especially searched for; the blood from the prick of the finger showed a normal tendency to clot, and the hemorrhage, which had recurred, instantly ceased when Dr. Robinson made a local application of a 4 per cent. solution of cocaine. The stomach was more retentive, and there were evidences of beginning convalescence.

The condition of the blood gradually improved, and an examination made two weeks later gave the following results: The blood emerged from the puncture freely, much more so than from a healthy individual. It was of a good color and coagulated slowly. Microscopically the blood presented a normal appearance, with the exception that there were rather more large red corpuscles than are ordinarily seen. The microcytes had entirely disappeared. The color of the red cells was somewhat paler than normal. The Fleishl hæmometer showed 70 per cent. of hæmoglobin and the hæmatokrit showed 84 per cent. of red cells. There was no leucocytosis.

At this time the finger was accidentally cut, and hemorrhage continued for thirty minutes despite the application of ice. When a 4 per cent. solution of cocaine was employed the bleeding was checked immediately, and did not recur.

Family history: The first child was born prematurely and died shortly after birth. The second child was a boy, who was perfectly well up to sixteen months old, at which time he began to bleed from the nose, and developed hydrocephalus at the age of three-and-a-half years. The attacks of epistaxis from which he suffered were frequent, severe, and uncontrollable. He would almost bleed to death, and then gradually recover. There were no other mucous membrane hemorrhages, and at no time was there purpura. This child finally died of hemorrhage from the nose. The third child was a boy, who was perfectly healthy until the age of two years, when he died within forty-eight hours

from malignant scarlet fever. At no time was there any tendency to hemorrhages nor evidence of hæmophilia. The fourth child was a boy, who died of hemorrhage from the mouth at the age of eighteen months. He was anæmic, poorly developed, and an eruption was observed upon the skin. The firsthe morrhage occurred when he began cutting teeth, and the quantity of blood lost was considerable. Later, when the molars were erupted, a fatal hemorrhage occurred, despite the use of every known means for its relief. The fifth child was a girl, who died at the age of three months without showing evidence of hæmophilia.

The mother of these children is one of a family of ten, all of whom were healthy. She has never shown any tendency to hemorrhages, with the exception that after the extraction of a tooth she observed that the amount of hemorrhage was greater than normal. This fact was well recognized by the dentist who would extract one tooth, but declined to remove a number at one time. The father has never shown any hæmophilic tendency, denies syphilis, and has always enjoyed good health. The maternal grandfather is said to have been "scrofulous," and had enlarged cervical glands, which might have been tubercular or syphilitic. With this exception the other members of this family, which are numerous, and may be traced to the third and fourth generations, have never known of a single case of the bleeders' disease. The father's family was also traced to the fourth generation, and the members of it were intelligent, healthy, and vigorous, not a single case of hæmophilia having occurred.

Remarks.—The cases are particularly interesting for the following reasons:

1. That each of these cases occurred in brothers.

2. That they all showed the first tendency to hæmophilia at an early age, particularly while teething. The oldest patient's trouble began with epistaxis, following an attack of cholera infantum, which may have been a gastro-intestine purpura. The first case is also interesting from its associations with arthritis, from the statement that frequently the hemorrhage would occur in forty-eight hours after an exposure which would excite a coincident attack of arthritis and fever.

3. The fact that slight trauma would produce extensive hemorrhage, proving that the blood vessel walls were remarkably fragile.

4. The extraordinary diminution of the coagulability of the blood.

5. The valuelessness of all the ordinary local remedies and agents for the relief of hemorrhage from the wound of the tongue, with the exception of the local influence of cocaine and ice and the internal administration of the fluid extract of ergot. We are disposed to attribute the greatest influence to the enormous loss of blood, by which not only was the fibrin increased, but also the peripheral circulation was slowed, so as to allow of the gradual formation of a thrombus. The use of cocaine as a local hæmostatic was suggested by Dr. W. Duffield Robinson. The remarkably brilliant results obtained in the first case lead us to hope that similar good may be obtained in other cases.

6. The occurrence of marked flushing of the face as a precursor of an attack of hemorrhage.

7. The opinion of the father that the intense nervous excitement produced by these violent pains in these attacks of arthritis may be a cause of epistaxis.

8. The greater frequency and violence of these hemorrhages since removal from an altitude of 1,800 feet to that of 2,200 feet, and the consequent deduction that hæmophilics should be removed to the sea level.

9. The occurrence of repeated attacks of acute arthritis with intense pain, redness and great swelling in association with fever and sweating, which are so frequently observed in hæmophilics, and the fact that they were erroneously diagnosed as attacks of rheumatism. The want of coagulability of the blood at the time of these acute outbreaks, their occurrence forty-eight hours after exposure to cold or damp, the frequent coincident occurrence of hemorrhage, and the absence of endocarditis, are all points in favor of the supposition that these were not attacks of rheumatic arthritis, but were hæmophilic in origin, perhaps due to the effusion of blood into the joints.

10. The second case is interesting from its association with hydrocephalus and the occurrence of death from epistaxis.

11. The third case illustrates the importance of teething in producing the first manifestations of hæmophilia, and shows how death may occur from this cause.

LOCAL ELECTROLYSIS AND ZINC-AMALGAM CATAPHORESIS IN MALIGNANT AND NON-MALIGNANT TUMORS.*

G. BETTON MASSEY,† M.D., PHILADELPHIA.

Before reporting the three cases on which this new treatment of morbid growths is mainly based I must explain what I mean by local electrolysis and zinc-amalgam cataphoresis, and also advance reasons for my belief that these methods either separately or together present important advantages over cutting operations in certain cases of benign vascular growths and incipient cancers.

Local electrolysis means simply that the electrical decomposition of the tissue salts is confined to a localized area by the approximation of the poles. If both poles of a galvanic current be placed in the morbid tissue quite near each other the bulk of the current will be concentrated within the portion of tissue immediately between them, and but little will traverse the outside healthy parts. In practice they should not be further apart than from a half to one inch, though this depends entirely on the strength of current to be used and the size of the growth. So placed, an enormous current may be employed to dissolve a morbid tissue without affecting surrounding tissues, the parts having been chilled by a spray, or otherwise rendered anesthetic, if sensitive. The surgical possibilities of such currents are quite remarkable. All the salts and liquids of a given growth lying between the points become a prey to such a current, the watery contents being turned into oxygen and hydrogen gases, and the complex salts into solutions of acids and alkalies. This is, of course, attended with a material rise of temperature, but nothing like charring. If the tissue subjected to the process is soft and vascular, or juicy, there will be very little left between the poles after the gas has been given off but the acids and alkaloids dissolved in a turbid liquid remainder. If the tissue is tougher and more fibrous a gristly residue will be found which can be detached or left to be detached by nature.

The strength of current required to destroy tissue in this way depends altogether on its concentration at the active spot. A minute reproduction of the process occurs when we apply but two or three milliampères to the papilla of a hair sheath, or to a mole on the skin; but to completely dissolve tissues between two or more needles a half inch apart requires at least four hundred to seven hundred milliampères.

Whether this portion of my method has any advantages over a cutting operation in removing malignant or non-malignant external growths depends upon circumstances. It is clearly inapplicable to any growth within the body unless it is situated in a drainable natural cavity, as a considerable quantity of detritus must drain away. It also presents the disadvantage of not permitting healthy tissues to be united at once over the seat of the removed growth, a procedure, however, that is often of doubtful utility, as it frequently covers up portions of the disease that failed to be removed. The advantages of the method over the knife are, on the other hand, by no means inconsiderable. It is absolutely bloodless, no matter where applied, thus enormously conserving strength after operations notoriously bloody; the edges of the undestroyed tissue remain non-absorbent, lessening risk of sepsis; and finally there seems to be some property in the galvanic current to cause a retrogression of the whole of a benign growth even when but a portion is directly acted on, as in the Apostoli treatment of fibroids and the ordinary treatment of moles and other small skin tumors.

If the growth be a benign one the application described will probably cover the whole of the active treatment. If it be malignant, on the contrary, the second portion of the method—zinc-amalgam cataphoresis—is employed, a procedure of great value in radically removing all re-

*Read before Philadelphia County Medical Society, January 9, 1895.

†Physician to the Gynecological Department of the Howard Hospital and to the Sanatorium for Diseases of Women and Diseases of the Nervous System, etc.

maining traces of a still localized cancerous growth.

Zinc-amalgam cataphoresis is electrically mono-polar, the single active electrode, which is always positive, being applied to the cavity left by removal of the greater portion of the growth, while the indifferent or negative electrode, in the shape of large conducting pads connected together, is placed on any convenient portion of the body. The active electrode is a freely-amalgamated zinc surface of one or two square centimetres area, which is held successively against all portions of the bottom and edge of the excavation. From 150 to 300 milliampères are sufficient, the pain being controlled by cocaine in solution placed in the excavation beneath the electrode, to be conveyed into the tissues simultaneously with the nascent oxychloride of zinc and mercury which is dissolved from the electrode by electrolysis.

By this procedure we search out and destroy all remaining spurs and paths of infection in the contiguous unhealthy and healthy tissues, the current seeking vascular and cellular paths of less resistance by preference in its journey to the other pole; and to the lethal effect of the current we add the well-known lethal effects of nascent mercury and zinc compounds. The surface of the amalgamated zinc electrode is consumed in the process—the mercury as well as the zinc—producing a mixed infiltration of the immediate polar region that is readily detected by the eye. Low organisms in the immediate neighborhood of the electrode quickly succumb, and the antiseptic value of the procedure is shown in the correction of any odors that may have accompanied the cancerous discharge. That the action is not confined to the immediate neighborhood of the electrode was well demonstrated in one case in which the zone-like base of a cancer was observed to lose its induration and shrink in places at least an inch distant from the contact point.

The applicability of the first portion of the method—local electrolysis—to a benign growth in the following case:

Case I. *Large intra-uterine cystic fibroid destroyed piecemeal by repeated applications of bipolar local electrolysis, resulting in a satisfactory cure.*—Mrs. D., a nullipara, aged thirty-nine, was referred to me by Drs. Hemminger and Bixler, of Carlisle, Pa., in September, 1892. Six or seven years previously Dr. Hemminger had discovered an intra-uterine growth, the lower portion of which later was found to be projecting from the dilated os, giving rise to pain and hemorrhage. Efforts to remove the growth by the écraseur were made by Dr. Hemminger, but, owing to its extensive internal attachment and great vascularity, only the projecting parts were removed. When the case was admitted to the Sanatorium the tumor was nearly the size of the adult head, the upper limit being even with the naval. The mass was symmetrical in shape, soft and semi-fluctuating. Examination showed the os fully dilated, through which projected a portion of the tumor the size of the fœtal head. Around this projecting mass several fingers could be swept, showing freedom from adhesion to the uterus for three inches anteriorly and about six inches posteriorly. The mass was evidently a vasculo-cystic fibroid situated within the cavity of the uterus and attached to the uterine walls throughout three-quarters of its periphery. It was spongy, but very tough, bled easily, and gave rise to a copious watery leucorrhœa. The conditions presented by this growth, particularly its cystic degeneration, absolutely contra-indicated the ordinary Apostoli treatment of fibroids on account of the danger of producing sepsis. I accordingly attempted its removal by morcellement, using the scissors, dull scalpel and fingers, but was compelled to desist, owing to the frightful hemorrhage. In this dilemma the possibilities of localized destructive electrolysis occurred to me, and it was begun by the use of a bipolar instrument having four prongs, two to each pole. These prongs were buried in the projecting portion of the tumor, and 700 milliampères turned on for six minutes. This dissolved quite a hole in the morbid tissue, making a spot too hot for the finger. The procedure was repeated daily as fresh portions of the growth were pressed down by the contracting uterus, without hemorrhage or marked discomfort, the possibility of sepsis being guarded against by a continuous douche for an hour or more after each application. Three months were consumed in the eradication of the tumor in this way, though it doubtless could be done in a second case in a third of the time, the final examination showing

nothing but a roughened spot on the anterior wall of the contracted uterus. External measurements now showed the upper limit of the uterus two and one-half inches below the naval. The cavity was capacious.

A letter from Dr. Bixler dated February 26, 1894, stated that the patient was quite restored to health, complaining only of prolapse of the vaginal walls, the latter doubtless due to the descent into the pelvis of a uterus that had so long been within the abdomen. The cavity was still large, and there was some thickening of the walls on both the right and left of the uterus. The os would only admit the first joint of the finger.

In November, 1894, two years after the patient's admission, her husband called and reported her as in good health.

CASE II. *Sarcoma of tonsil and soft palate cured by local electrolysis, followed by zinc-amalgam cataphoresis.*—W. H. L., blacksmith, aged thirty-eight, was also referred to me by Dr. Hemminger, February 17, 1893. Five years before he suffered from an abscess of the ear. Two years before being seen by me the left tonsil was found to be the seat of a tumor. He had recently been sent to the Hospital of the University of Pennsylvania, where, he says, malignancy was diagnosed and an operation proposed, which he declined.

A tumor about the size of a goose egg filled the pharnyx, involving the tonsil and soft palate, and threatening suffocation. Liquids could be swallowed with much difficulty.

The patient was placed on monopolar negative punctures, 30 to 60 milliampères, daily. But little progress being apparent at the end of a week, the parts were cocainized and subjected to bipolar local electrolysis with from 200 to 350 milliampères, on two occasions. The separation of the eschar that resulted was accompanied by considerable pain and reaction, but as the place healed it was found that but little of the tumor remained. He did not return for further treatment until more than a year had elapsed, during which he seemed to be well. At this time, however, a renewal of the growth occurred, and it was about the size of a peach-stone when he was readmitted to the Howard Hospital for further treatment. During this second treatment zinc-amalgam cataphoresis was mainly employed, the treatment lasting six weeks and being carried deeply into the base of the growth. A complete cure resulted, and at an examination of the parts six months later a healthy scar only was to be seen.

CASE III. *Inoperable carcinoma of the groin greatly relieved by zinc-amalgam cataphoresis; death from erosion of femoral artery and gangrene.*—Colonel H., aged sixty-two, was sent to me by Dr. A. W. KNOX, of Raleigh, N. C., in the summer of 1893. One year before he had noticed a lump in the left groin. On admission to the Sanatorium the tumor was the size of a large walnut, of a bluish color, and firmly attached by a broad base to the deeper parts of the thigh. It was situated just below Poupart's ligament and lay immediately over the femoral artery and vein, and was apparently attached to the latter, though the exact location of the artery was uncertain owing to the general induration.

At the patient's request it was decided to make a tentative use of electricity. The central and projecting portion was accordingly destroyed by local electrolysis, making a slight cavity into which a solution of cocaine was poured. Into this the blunt amalgamated zinc electrode was pressed and daily applications of the cataphoresis made, with currents averaging 150 milliampères. The immediate effect of the application was to whiten the edge of the growth in contact with the electrode, the whitened coating peeling off later. The indurated ring and base that now represented the growth was about three inches wide. Under constant applications the whole of this was gradually destroyed and replaced by healthy granulations, except the center of the base, where the close proximity of the large artery rendered the applications unwise. At the end of three months the diseased area had been contracted to the size of a five-cent piece, but this was a deep cavity extending down to the great vessels, where it was thought to be unsafe to apply the current. The patient had increased twenty pounds in weight, and though brought to the Sanatorium on a stretcher, was now able to walk a half mile or more. During the continuance of this improved condition, however, the artery suddenly gave way one day at the bottom of the untreated spot. Drs. Thomas S. K. and T. G.

Morton were called in and tied both artery and vein, which were found thoroughly infiltrated with cancerous material for some distance upward into the abdomen. Gangrene of the limb supervened, followed by death two weeks later.

An estimate of the value of the method in these three cases must be comparative, as cases similar to each are usually subjected to other methods, removal with the knife being the favorite. Hysterectomy in the first case would, of course, have involved removal of the ovaries also. Both this and removal of the uterus itself were avoided entirely, no natural structures being even injured, and the time required in the treatment was probably not longer than that necessary to recovery from the effects of abdominal section. In the second case the bloodless removal of a sarcoma of the palate was followed by a treatment that I hope will render the patient less liable to a return of the disease. The third case was, of course, a failure to cure or to preserve life, yet it is thought that life was prolonged by the very evident curtailment of the growth and improvement of health. Comparisons were hardly possible, however, as an operation had been refused by one surgeon as useless.

ILLITERATE BOORS IN THE PROFESSION.

The *Texas Health Journal* provides its readers with the following treat:

The Cheap-John medical colleges and reckless medical examining boards of the country are daily turning out large numbers of ignorant fellows with the title of M.D., who are a burning shame and disgrace to the noble profession of medicine. This is not all. They are dangerous to the public welfare. Who is to blame? The colleges and boards who, for a paltry sum, permit these fellows to roam at large. These colleges and boards are always "ethical." Certainly each and every one must endorse the code of ethics or he is not eligible for the position in a college or on a board. I give below a letter sent me by Dr. H. Riley, of Bowie, Texas, and written by one of these boors to the postmaster at Bowie. It is only one of many such letters sent the *Journal*. The *Journal* occasionaly publishes such letters with the hope of raising the standard of medical education by holding colleges and boards up to shame, as they deserve. The following is a verbatim copy of the letter written from Memphis, Texas, to the postmaster at Bowie by an alleged "doctor:"

MEMPHIS Hall co texas 12—2—93

MR. POSTMASTER AT BOOEY

Please tell me what the popolation of yor town is and how meney Dos thair is thair and is the soronding coontrey a fertill coontrey or not and eff yo have soft water &. doo yos Rais corne & oats & cotton il not ask aney more questions as . i may wairey yos with questions. I am in the Pan handle trying too dispose of some cattle after so dooing i am Ready for .a. Location whair thair is sChools .& Churchis . i am 51 yairs of age have a wife & 1 grone sone. &. 3 small boys all too school. i. am from Lee. co. Missippi hop yo will anser this and oblige at once

i am not very ancios to Locat in town i am a. graduat of Medison and sergery so acknowledg By the state Board of Texas

Respectfoly,

Dr. T. G. H.

An Early Grave Complication of Pharyngeal Diphtheria.

Aufrecht, *Therapeutische Monatshefte*, calls attention to a particular form of diphtheria of the pharynx, which despite its limited local extension, rapidly kills the patient in two or three days. It has been held that these almost fondroyant cases were to be attributed to a grave infectious myocarditis. Recently, however, the author has observed three cases of this kind where the autopsy showed no trace of myocarditis, but a sub-acute nephritis. The author, therefore, insists upon the importance of systematic examination of the urine from the beginning of diphtheria, even when no symptom points to a renal lesion. The symptoms observed in these cases have been very great frequency of pulse, a semi-comatose condition, delirium, high fever, and marked albuminuria. Guided by these cases the author has been able in a fourth case to combat this nephritis in the beginning by the administration of large quantities of alkaline and saline water (Wildungen) for the purpose of increasing diuresis and relieving the chocked-up kidneys.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable to the Publisher only, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We invite contributions of value to the profession, and if published originally in THE REPORTER such will be paid for at liberal rates, or a limited number of copies of THE REPORTER will be supplied, as the author may elect. Hereafter where reprints are desired writers are requested to make a note of that fact on the first page of the MS., but must order reprints directly from the publisher, who will supply the same at cost rates. Contributors should inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, MARCH 16, 1895.

EDITORIAL.

LARGESSE! LARGESSE!
THE INSPIRATION OF PROFESSIONAL PHILANTHROPY.

With the assembling of each new legislature of this State, there is an invasion aptly described by the old nursery rhyme:—

"Hark! Hark! The dogs do bark.
"The beggars are coming to town.
"Some with rags, some with 'jags,'
"And some with silken gowns."

On every hand is the cry for "Buck-sheesh!" and appeals for "Largesse!" That the almoners of the common-wealth have been bewildered, befuddled, cajoled or convinced is demonstrated by the official records, which show an undue proportion of the public bounty bestowed upon undeservers, to the great detriment of the truly needy. Reference is made to state appropriations for private hospitals, particularly to those of this city, and the unfortunate provisions for some comtemptible productions of *Professional Philanthropy*, while the necessities of the State's own wards are barely supplied.

Our friend, *The Medical News*, accepting the risk of making itself to be disliked by interested parties, presents some interesting figures, with some strong editorial comments which we are glad to repeat and to endorse:

"Before the Pennsylvania State Legislature the various charitable institutions have laid their applications for appropriations for the years 1895 and 1896. The amounts asked for by hospitals of the third class, that is, hospitals owned and controlled by private corporations, are

For the year 1895	$1,446,211 93
" " " 1896	1,019,500 00

"About one-half of this is for new buildings or for removing debts of mortgage, and one-half for maintenance.

"When an individual endows a bed in a hospital he has a right to send anyone there, at any time, to occupy such a bed. When the State gives a grant of $50,000 it virtually endows ten beds, yet does not possess any right to such beds. The only place a poor incurable tuberculous or other invalid needing the attention a hospital can give has a right to go is the

Philadelphia Hospital, and here, alas, there is but little room for him.

"The private hospitals obtain their appropriations only through strong lobbying, and if a charity has a "pull" it can get almost anything it wants.

"A few individuals organize a hospital, largely and principally for their own benefit, and then obtain appropriations from the Legislature, by which they can erect costly buildings and bring themselves into prominence.

"If institutions are to receive State aid, they should be under State control, and where it is found that over-lapping exists, that one institution can do the work of two, the other should be dropped from the State list.

"The following Philadelphia hospitals are represented in the applications:

Name of hospital.	Amount asked for 1895.	Amount asked for 1896.	Amount received in past six years.
Hahnemann	$67,000	$50.000	$73,546
University	50,000	50,000	135,000, 4 yrs.
" Maternity	5,000	5,000	
" Veterinary	5,000	5,000	30,000, 4 yrs.
St. Timothy's	12,500	12,500	7,000, 2 yrs.
Kensington, for Women	13,500	5,000	5,000, 2 yrs.
Polyclinic	25,000	25,000	87,000,
Jefferson	50,000	50,000	130,000
Woman's	25,000	25,000	25,000
Howard	2,500	2,500	
Medico-Chirurgical	82,500	82,500	170,000
Rush Hospital	75,000	75,000	
West Phila., for Women	12,500	12,500	
Women's Homeopathic	17,400	17,400	67,000
Children's "	17,000	17,000	8,000, 2 yrs.
St. Christopher's	5,000	5.000	
Philad'a Lying-in Charity	7,500	7,500	15,000
Southeastern Dispensary	2,500	2,500	
Orthopedic	23,500	23,500	30,000
Maternity	8,000	5,000	15,000
Gynecean	20,000	15,000	85,000
Wills Eye	10,000	10,000	40,000, 4 yrs.
Samaritan	30,000	30,000	
German	10,000	10,000	40,000, 4 yrs.
Hospital for Incurables	20,000	20,000	

"It will be noticed that all of the foregoing institutions, with the exception of Wills Eye Hospital, which is in trust of the city, are strictly private concerns. They are not obliged to render account to any public official. The funds received may or may not be applied to the purposes for which they are asked.

The Governor has but recently stated that economy is necessary in the affairs of the State. Let the Appropriation Committee turn to the private hospitals first.

"We want a State Hospital for Epileptics and two or three for tuberculosis, but let these be managed by the State as the hospitals for the insane are.

"We hope that the medical profession of Pennsylvania will enter a protest against indiscriminate grants to private charities, and ask that State moneys be applied to institutions under State control."

THE REPORTER agrees with these views. There is neither wisdom nor propriety in delegating the expenditure of public funds to persons or institutions not under the controlling supervision of the State authorities—not even accountable for the use made of the people's money.

We do not in any sense condemn private hospitals, but we call attention to the broad distinction between hospitals private, as popularly understood, and private as defined by the Legislature. The former are provided and conducted by one or more individuals entirely at their own personal expense; the latter are enterprises originated and manipulated in the interest of individuals but entirely without expense to them personally. These private hospitals are usually corporate bodies professedly dependent for support upon voluntary contributions of the community.

They are not necessarily unworthy of aid. Indeed, many of them are deserving of most generous support, but it should not come from public funds unless the State is able to compel the proper expenditure of the money granted.

However, since private hospitals have been and will be afforded aid by the State, the keenest discrimination should be made against the speculations of Professional Philanthropy.

A prominent member of the Lower House is authority for the statement that the entire amount at the disposal of the present Legislature will scarcely exceed $9,000,000. Of this sum five and one-half millions must be devoted to the public schools, and out of the balance must be paid all other expenses whatsoever, incurred by the State Government, including such appropriations as may be made to applicants for State aid. Under the circumstances there would seem but little chance for helping private institutions, although these institutions when applying for stated amounts fully expect a reduction of from thirty to fifty per cent., and provide for this discount in making their application, so that if the anticipated discount is made they will receive all that was really hoped for when making application.

Before any application of the third class is entertained, the institutions that are directly managed by the State should be liberally provided for; if anything remains, those institutions over which the State has partial control should receive consideration; and in the improbable event of a surplus, careful attention may be given to the private hospitals. Under no consideration should assistance be granted to the projects of Private Philanthropy.

The list above, which we quote, furnishes two excellent specimens of applicants, who, however worthy in other respects, are not at all deserving of aid from the public treasury. It is not necessary to specify these hospitals by name; many of their disqualifying conditions apply equally well to others here and in other parts of the State. One is an habitual parasite; the other is a perfect type of Professional Philanthropic invention.

In the first instance, the hospital is one of three distinct divisions of a corporation whose charter authorizes and empowers it to maintain the hospital; a home for the support of the aged, male and female, of a specified nationality; and an institution for the maintenance and education of a religious order; and to receive donations, legacies, etc., etc., and apply the same to the *general* corporate purposes without distinction. The institution, unquestionably, is sectarian. Its by-laws require all business to be transacted and records to be kept in a foreign language. Its patronage is very extensive among a well-to-do class of people. It makes ample provision for its own support by a system of initiation fees, membership dues, fees from patients, and subscriptions of individuals and associations, and, quite recently, it has incurred the displeasure and distrust of the profession by advertising in the daily papers to establish and conduct the vicious "contract" system, which has so impoverished the medical profession abroad. This institution, which is sectarian, which has sufficient means to build, endow and support from a common income, two other institutions of considerable magnitude but entirely foreign to the purposes of a hospital—this *private* hospital has begged and during a very few years obtained alms from the State amounting to thousands of dollars, and for no reason comprehensible outside of the politician's consulting room. Having secured money so easily, the institution naturally comes back for more. We violate no confidence in stating the accepted opinion that, once on the State beggar's list, an institution will never be refused absolutely (or deservedly), so long

as there remains any of the people's money or credit.

As for the second outrage upon decency, the Professional Philanthrophy Pudding, the explanation is very simple in view of the customs of political courtesy. But the premeditated misprision of legislative duty is enormously aggravated when to ineligibility there is added the fact that the applicant is the embodied presentment of Professional Philanthropy.

It is not possible to give a definition of Professional Philanthropy which would be, at once, brief and sufficiently comprehensive. One conception would be, the art of requiring reputation for the love of fellowman and for devotion to his relief and salvation, by appropriating to self all credit for the results of efforts wholly of others who are too modest to blow their own trumpets and whose work can be patronized and applauded without any self-sacrifice or personal expense. But this is merely a single phase. Professional Philanthropy is a congeries of characteristics or traits, no one of which is peculiar to this form of mental and moral obliquity, and all of which rarely or never occur in the person of any one individual Professional Philanthropist. There is, however, one constant feature—the absolute lack of self-sacrifice. It is the constant predominating of this quality which characterizes all genuine philanthropy. Herein is the distinction between philanthropy and Professional Philanthropy.

Perhaps a sketch, drawn from life, of an eminent Professional Philanthropist will give the best definition of the term:

Male, in the prime of life; moving in the swellest social circles—the froth; a pillar in the church on Sundays; rated high financially; director in several of the solid moneyed corporations of the community; wealthy by inheritance, by business ability, and by acquirement; prominent in public affairs not requiring personal expense; manager, trustee, governor, or what not, in a variety of charitable institutions; controlling the affairs of at least one richly-endowed charity (including its finances, cash, bonds, stocks, and real estate, its work, its policy, its officers, its elections, and even the opinions of the boards of alleged managers). So far one might be in fact philanthropic save for a little too much self-consideration, but now the modifying qualities which distinguish the Professional Philanthropist obtrude themselves very offensively. For instance, the founder and endower of an institution, when devising his entire property in trust for the realization of his efforts to benefit the unfortunate and needy in the field of his life work, evidently took it for granted that the men he chose to carry out his intentions were as humanely disposed as himself (or should be, since it would cost them nothing but a little thought and time to do a great amount of good), for he made no provision for paying his trustees' salaries for their services, but specifically desired that such service be without remuneration. It required an amendment to the charter to accomplish it, but Professional Philanthropy set a cash value upon its name and service and secured the necessary change, at least for some offices, and then secured the offices. In the course of financial affairs, securities depreciated and some retrenchment became necessary. This was easily accomplished in such manner as employers are accustomed to reduce expenses in business by retrenching the incomes of subordinates and employees. So that, as the matter now stands, Professional Philanthropy, working possibly twenty-four hours during the year, has a money value far in excess of that of the services rendered by the practical executive of the whole institution, who works twelve hours a day three hundred and sixty-five days, and averages perhaps four hours a night for three hundred and sixty-five nights, and who bears the responsibility of the details

of management as well as the cares and worriment of the professional duties. Again, the "nominal" remuneration for shedding the light of his Professionally Philanthropic countenance on the sorrows and burdens of the unfortunates who come within range is munificent compared to the sum total given to all charities combined, so far as is discovered by the reports of the various treasurers made public. In the few instances where it occurs, its name is displayed in bold faced type, so to speak, and leaves the impression that one dollar wrung from Professional Philanthrophy is a greater triumph for good than one thousand dollars dropped from the free hand of Generosity.

A lawyer might explain away this suggestive fact, but he would find it hard work to rub out the adjective, Professional, from the degree of the Philanthropist who regards the beneficiaries of a trust as a species of mankind peculiar, grading socially lower than the swiftly changing retinue of servants in his own home, and as singularly unsuited for any comforts or conveniences not found in the back kitchen or stable loft and, more than all, treats them so.

He is a Philanthropist for what there is in it, not for what he puts in it.

Four or five such humanitarian, sassociating themselves with one philanthropist for the sake of the money necessary to start with, incorporate and launch a new charity in the shape of a hospital. The inspiration of the act is generally found to be a desire to provide occupation for some incompetent but dependent relative or other social equal, whose light otherwise must be hidden under a tea-cup. The confidence manifested will be found due to access to the public treasury provided with the assistance of some one who has been there before, and who is bound to see that they get there too. Once successful in reaching this source of support, Professional Philanthrophy has demonstrated its power for doing good, by providing subsistence for at least one incompetent, who otherwise might be thrown for support upon the county authorities. This demonstrates not only a kind heart, but a level head, for it is evident that it is more economical for the State to support a pauper than for the County to do so, the tax being less per capita.

This is a brief and crude summary of the character of a protege of Professional Philanthropy which already has disposed of scores of thousands of the public's dollars without rendering any visible consideration.

If the Legislature is able to overcome its blind devotion to political courtesy long enough to refuse an appropriation to this bottomless pit which can never be filled, either the Professionally Philanthropic sponsors will have to return more of their "remunerations" from charities to charity, or the long-felt want for which this hospital was provided will be found fully satisfied, the institution will lay it down to pleasant dreams, and suffering humanity will find in its closed doors cause for rejoicing that, in one instance, true philanthropy has finally triumphed.

Two Easy and Delicate Tests for Albumin in Urine.

Dr. C. Fouchlos (*Progres Medical*) recommends two new tests for albumin in urine, for which he claims utmost delicacy and absence of any possible fallacy.

1. Add to the suspected urine a few drops of a one per cent. solution of corrosive sublimate; in case of turbidity, add some drops of acetic acid. If the turbidity persists it is due to the presence of albumin.

2. Take 100 cc. of a ten per cent. solution of sulpho-cyanide of potassium, and mix with it 20 cc. of acetic acid. Add a few drops of this mixture to the urine. If albumin is present in small quantities, an immediate turbidity will ensue; if in larger quantities, a heavy white precipitate will appear.

ABSTRACTS.

"AURAL MASSAGE."

Laurence Turnbull, writing (*Med. News*) of its value in the treatment of various diseases of the ear, says:

"Aural massage," by alternately moving backward and forward the auricle with the opened and closed meatus, by the hands, with associate movement of the sterno-cleido-mastoid and occipital muscles, has been recommended and practiced for some time for the purpose of giving freedom to the membrana tympani when adherent and thickened, and with some benefit, also, in certain diseased conditions of the other parts of the ear. Another method is to open and shut the orifice of the canal by pressure on the tragus at its lower part, closing the meatus with the thumb or forefinger; the force may be increased by greasing the canal with vaseline alone or with medicated ointments or oils. There is also a more perfect method of massage, by condensation and rarefaction, by means of the instrument of Siegle, which has for years been employed in the examination of the membrana tympani. It resembles the ordinary hard-rubber speculum, but is more elongated, and its outer opening is fitted with an oblique plate of glass. A small nipple projecting from its side marks an opening to which is attached a small rubber tube ending in a mouthpiece. The instrument is used by inserting the small specular end into the meatus as far as possible (best covered with a section of rubber tubing and anointed). The mouth is applied to the end of the tube, or a small syringe, to exhaust the air, may be employed, or else an elastic valve bulb can be used; through the glass the movements of the membrana can be watched. All these plans were very unsatisfactory and could not be graded until Dr. Chas. Delstanchè, of Brussels, gave us two improved instruments, only a brief description of which I can give at this time, as they require cuts to fully illustrate them.

Delstanchè's instrument for massage, or as he terms it "masseur," consists of a metallic tube enclosing a smaller tube of metal which acts like the valve of a syringe. The recoil of the valve which produces the aspiration and condensation is accomplished by a spiral spring between the valve and the bottom of the metallic tube. The inner tube is graduated in fifths, so that one may determine by a key the amount of power to be employed. Care is necessary in the use of the instrument for fear of rupturing the drum-membrane, causing a great deal of pain, a flow of blood and an interference with the operation. In order to better condense the air in the tube the nipple-like process is covered with rubber. It must then be withdrawn from time to time, but the to-and-fro motion may be kept up for some time to advantage, always examining its effects upon the membrana tympani. The other instrument is named by Delstanchè the "rarefacteur." It is provided with a double valve, and has an advantage over the other instrument in that, without removing the stop-cock, one may alternately condense and rarefy the air in the external meatus, or rarefy it alone. It is much more powerful, and with it we can rarefy the air in catarrhs of the middle ear and Eustachian tube, in which there is a sunken membrane, or break up adhesions between the membrana tympani and inner wall of the cavity of the tympanum, or after paracentesis of the membrane, when we have fluid products to be removed.

Several other instruments have been brought forth of late for the same purpose, differing in name, but all of them having the same object in view; they cannot be employed alone, but as an aid to other means, for although they are of value when properly applied by the scientific and aural surgeon, they are of limited application, and like all efficient agents can do harm as well as good.

One of the most recent of these instruments has been termed the "vibrometer," which combines massage by sounds, both mechanic and electric, with exhaustion or rarefaction, with a series of musical strings. The first instrument employed was like a violin; the second like a guitar;

the last in the form of a banjo. This latter instrument is termed a vibrometer. A medical friend made a series of experiments with the first one hundred cases* of tinnitus aurium and deafness, but only two per cent. were successful in relieving the patients, and my own efforts have been as resultless. Ten cases out of one hundred will be reported. These will be sufficient for our purpose; they have not been selected but are like the ordinary cases that present themselves to the aurist every day for treatment.

The following are the rules for the use of the instruments employed, after making a careful diagnosis, and correcting, as far as we are able, defects that would interfere with the successful use of the instrument:

The length of the sittings is from five to twenty minutes, and the number two a week. For tinnitus, like the ringing of bells, the chirping of insects, the singing of birds, the sound of escaping steam, try the highest notes of the instrument, say twenty thousand vibrations a second. Draw the fine musical string of the vibrometer very tight, and shorten it with a clamp to obtain high notes; to obtain low notes elongate the strings. When the tinnitus gives a deep sound like a sewing machine, the humming of a saw-mill, and for all low-pitched sounds, use the low-toned strings, say of forty vibrations a second, and the pounding arrangement with the so-termed exhausting wooden plate. When the tinnitus is high, increase the vibrations up even to thousands. When the right pitch has been obtained the patient should only hear one sound, and the noises which he hears continually should be gone. In the case of a physician who suffered with constant tinnitus he was able by the use of the vibrometer to get rid of it, but he required the constant use of the instrument, as the tinnitus would return.

There are three other methods now in use for stimulating the deaf ear, all of which I have examined and employed alone with no better success: namely, the vibrophone, audiphone, and the musical-box and pressure-probe.

When "very deaf" patients cannot bear rough, grating, or shrill sounds, a pleasant agency is a small music box (Cohen), on which is placed a cushion, and upon this the patient places the deaf ear, so that contact with it occurs every day for ten or fifteen minutes; this is to increase the mobility of the ossicles. Lucae has recommended an apparatus for increasing the mobility of the auditory ossicles in cases in which there is stiffness (ankylosis) accompanying a form of deafness in which the patient is not able to hear general conversation, and Rinne's experiment yields a negative result. It consists of a steel rod, or pin, at one end of which is a small conical depression for the reception of the short process. The pin goes through a conducting tube, and its other end touches a spiral spring fixed into the handle of the instrument, and yielding readily to pressure. In employing this "pressure-probe," or feathered sound, the patient's head is first fixed and the instrument introduced under a good light along the upper wall of the auditory canal toward the short process of the malleus. The latter is received in the hollow at the inner end of the probe, and sharp taps are then made against it; at first, one or two only, later, up to ten, to be repeated if the result is favorable. Lucae asserts (Gruber) that after the employment of this instrument the air-douche may be used with success. As almost all patients suffer pain on the slightest touch with a fine probe, a solution of cocaine must be employed prior to the operation. The tip should also be covered with delicate oilskin, else it will be found that excoriations will be produced. This operation is only justifiable in the hands of the competent aurist who is perfectly familiar with the parts. Improvement, which in some cases takes place after this painful operation, cannot be relied upon without treating the middle ear at the same time.

*Private statement; the cases are not yet reported.

To Lubricate Catheters.

The Paris correspondent of the Lancet says that Professor Guyon, of the Necker Hospital, uses the following formula:

Bichloride mercury	gr j
Glycerin	āā 5ij
Water	
Powered soap	5iv—M.

This ointment is claimed to be unirritating to the urethra, and to possess greater lubricating power than either oil or glycerin—*Virginia Medical Monthly.*

SOCIETY REPORTS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

January 9, 1895.

Drs. Daland and Robinson presented a

A CLINICAL STUDY OF THREE CASES OF SPONTANEOUS HÆMOPHILIA IN BROTHERS.

(See page 376.)

DISCUSSION.

DR. FREDERICK P. HENRY: Isolated cases such as have been described to-night are rare. It is generally possible to demonstrate the hereditary character of this affection, which is in reality the most hereditary of all diseases. There is in Switzerland a family of which the history has been traced for about three hundred years, and during this period there have been bleeders among the male descendants. The females, as a rule, remain exempt, the disease being transmitted through them to their male children. They are not necessarily exempt. Virchow believes that one woman may be affected to seven men in families of bleeders.

There are certain peculiarities about families of bleeders, and one is their fecundity. The decimation in numbers, caused by fatal hemorrhages, is made up to a certain extent by the fecundity of the females. Dr. Daland stated that in this case the mother was one of ten, and there have been counted two hundred and four children in twenty-one families of bleeders, giving a large percentage for each mother.

The disease has been supposed to be more prevalent among certain races, especially the Israelitish race. I think, myself, that this supposed predisposition would disappear if all infants were subjected to the traumatism which is an integral part of the Jewish ritual.

Symptoms. These were cases of spontaneous bleeding, but this does not remove them from the category of hæmophilia. It has been stated that the spontaneous form is more intractable than the traumatic variety, but I am inclined to doubt the truth of this statement. Dr. Daland referred to the flushing of the face prior to an attack of bleeding; this is an old observation. Signs of cerebral congestion have been repeatedly observed in these case. It is manifested not only by flushing of the face but by subjective signs, especially tinnitus aurium, and in the days in which bleeding was practiced phlebotomy was performed at this stage, and it is stated that the incision into the vein was not attended with severe bleeding when made in this prodromal stage of the affection.

The rheumatoid symptoms are interesting. They have been observed in nearly all of these cases, and have been attributed to hemorrhage into the joint, but in no case with which I am acquainted has blood been found in the joint post-mortem.

There is one affection that has been confounded with hæmophilia, but is not likely to be in these days, and that is leucocythæmia, when attended with the subcutaneous extravasation of blood.

The prognosis after the age of twenty-one is good. The tendency to obstinate hemorrhage seems to diminish after that period.

The cause of the affection, I believe, is to be found in the blood vessels rather than in the blood itself, and yet I make that statement with a certain reserve, because the treatment which has been found most satisfactory rather contradicts that assertion. Microscopic changes have, however, been found in the arterioles, consisting mainly in wasting or absence of the middle muscular tunic of the vessel. Vasomotor influences undoubtedly play their part in bringing about an attack. This is shown by the flushing of the face, which so often precedes an attack, and also by the fact that the attack may follow emotional excitement.

The treatment is both prophylactic and curative, and one element is undoubtedly

climatic. Dr. Daland's patient improved when removed from a high altitude to a lower. In recorded instances patients have been free from attacks in southern Europe, while they had repeated attacks in northern Europe. The disease is essentially one of cold climates.

There is one remedy which has been employed for nearly one hundred years.

This was recommended by Dr. John C. Otto, of this city, who was one of the first to write on the subject of hæmophilia. America deserves the credit, and has been given it, of having been the first to demonstrate the hereditary character of this affection, and one of the earliest writers on the subject was Dr. John C. Otto. His paper is to be found in the *Medical Repository* for 1803. He employed the sulphate of sodium in repeated purgative doses, and claimed that it was efficacious, especially in the early stage of the affection. Ergot and turpentine have also been used. The latter has been efficacious in quite a number of cases. The hydrastis canadensis has also been successfully employed. Probably the best of all remedies is the transfusion of entire blood, and the amount required to control the hemorrhage is exceedingly small. A few ounces will sometimes suffice. It is supposed that the entire blood furnishes to the circulating fluid the element in which it is deficient. This is supposed by Hayem, of Paris, to be the hæmatoblasts, or blood-plaques, which are so prominently concerned in the act of coagulation.

Dr. Thomas D. Dunn, of West Chester: I have long been interested in the subject of hæmophilla, having had knowledge of such a case when a schoolboy of thirteen. The more that I have studied hæmophilla the more have I been convinced of its hereditary nature. In many cases where the disease is supposed to have developed spontaneously in families, further investigation may show that the disease existed in previous generations. Sometime ago I reported to the College of Physicians a case of purpura hemorrhagica in a boy who had had several large hemorrhages, one from the opening of an axillary abscess and another from the extraction of a tooth. I exhibit a photograph showing the appearance on the eight day of the attack of purpura.

Hæmophilia is a disease which has been recognized for a great many years. The first record is by an Arabian physician, in 1107. Isolated cases then occurred from time to time, especially in the Jewish race, but later investigations show that it is largely an Anglo-Germanic disease.

As to the hereditary character of the disease, Grandidier, in 1855, collected 213 families in which there were 631 subjects of the disease. The 120 cases that I collected occured in 37 families. Immermann collected 19 cases in 6 families, making in all 770 cases in 256 families, or about 3 bleeders to every family. In 1883 I reported a remarkable family of bleeders under the name of the Worrall-Garrett famiiy. Some members of this family I was unable to find. Later I visited a lady in Delaware County who gave me a letter describing a hemorrhage which her father had had following the extraction of a tooth. This was in 1827, and an account of the case was published in a Philadelphia journal in Jannary, 1828. Although two generations had been skipped, the disease again appeared. There were four sons, and three died of hemorrhage. The one that remained was not a bleeder. This was the grandfather of the child whose picture I have shown. The father never showed any tendency to bleeding, but another child in the same family has had many violent hemorrhages, both spontaneous and traumatic.

Dr. Henry referred to the frequency of the affection among males. I think that about 8 per cent. of the patients are females. One remarkable feature is that the children of non-bleeding men and women are more apt to bleed than the children of bleeders.

The prognosis in young children is very grave indeed. Of the 16 deaths occurring in the families that I reported in 1883, 9 occurred before the eight year. Of the 212 deaths reported by Grandidier, 111 occurred before the seventh year. This shows the remarkable mortality in the early period of the disease. It is equally remarkable how early the disease develops. Thirty-six of the 38 cases that I collected showed manifestations before the age of eight years.

Treatment. I think that no female in a bleeder family should marry, whether she is herself a bleeder or not. It seems that the bleeder brothers who bleed themselves

are less likely to transmit the tendency than the non-bleeding brothers.

The remedies usually employed in the treatment of hæmophilia have been referred to to night. I have never had an opportunity of trying cocaine. The tincture of the chloride of iron has been used with benefit. I am positive that I have seen benefit from the use of sulphate of sodium, and this agent has been found valuable by several German observers.

In regard to the surgical aspect one very remarkable point is, that very few serious hemorrhages follow major operations in these cases. There seems to be less danger from extensive than from trifling wounds.

Dr. Ernest Laplace: I saw a case of this kind in von Bergmann's clinic in Berlin. A man came in to have circumcision performed. The bleeding was free and hæmostatics were applied. Finally, sutures were employed, but the man finally died at the end of a week from the results of the hemorrhage.

Dr. De Forest Willard: I have had one unfortunate experience in a case of erosion of the knee, where the mother failed to inform me that there was any hæmophilic difficulty. The condition was apparently one of ordinary tubercular arthritis. At the time of operation I found the gelatinous material tinged red and some free blood in the joint; I also had great difficulty in controlling the hemorrhage. Bleeding occurred on the night of the operation and the following day, and continued until the child's death, a week afterward. Every method was attempted for its control, but proved ineffectual, as the oozing steadily continued. The mother afterward stated that she knew that the child bled easily, but had never heard of such a condition as "bleeder's disease." I have seen another somewhat similar case in a girl of thirteen, but which did not prove fatal.

Erigeron canadensis does not seem to have the same effect in these cases as in other forms of bleeding. For nasal hemorrhages I rely entirely on erigeron, and have not plugged the nares for years.

Dr. Judson Daland: I have been much gratified by the dull discussion on this interesting disease. A number of facts have been brought out that had escaped my attention. My own experience has been limited to the cases reported.

The observation of Dr. Robinson in regard to the hæmostatic action of cocaine is of great practical importance. The results in these cases seem to be more than a mere coincidence, and cocaine deserves a trial in subsequent cases.

It was on account of the great rarity of spontaneous cases that I made extensive inquiries as to the possibility of the disease occurring in former generations. I was able to inquire into the family history as far as the fourth generation, but failed to discover any similar cases. It is, of course, possible that some more ancient ancestor may have transmitted the disease, and these cases would, therefore, be examples of indirect atavism.

I was interested in the vasomotor symptoms of hæmophilia. These were so distinct in the case under discussion that the father was able to predict a hemorrhage from the flushed condition of the face and attendant nervous excitement. This fact perhaps indicates one of the methods by which hemorrhage may be initiated. The capillaries and smaller arterioles may be the seat of congenital changes rendering them usually vulunerable, and the mere act of dilatation may, in some cases, be sufficient to cause rupture.

The prognosis increases in favorableness directly as the years. This boy having lived to the age of thirteen years, we gave a guardedly favorable prognosis.

As regards the pathology of this strange disease, Dr. Henry is inclined to think that the chief factor is a morbid state of the walls of the blood vessels. The evidence points strongly to a curious fragility of the blood vessel wall. This particular case proves that we have a second factor, namely, that the blood has a diminished power of coagulation.

The suggestion with regard to transfusion is an important one, and this should be resorted to in obstinate casses.

In regard to the oil of erigeron, I would say that it was employed, but proved valueless.

This case showed so prominently the symptoms of rheumatism that I should like to mention a differential point of importance, and one that is new—namely, that in rheumatism we have uniformly, whether the rheumatism be acute or chronic, a remarkable increase in the coagubility of the blood. The almost total absence of coagubility noted in our patient

would, therefore, be of importance in excluding rheumatism and strengthening the opinion that the joint affection was hæmophilic in nature.

Dr. James C. Wilson: In a disease so rare as this it is desirable that personal experiences, although not very exact in detail, should be brought forward. In 1872 I saw a young man suffering from hæmophilia in the Pennsylvania Hospital. He had been carrying a crock and had tripped and fallen on it in such a way that one of the fragments struck him in the face, passing in front of the incisor teeth, cutting the mouth, and making a small wound. No arterial twig of any importance had been divided. He had bled for some days before coming into the hospital. He was taken to the surgical ward and the ordinary methods for the control of hemorrhage employed. I have a vivid recollection of the surprise and disappointment of the staff at the failure to control the oozing. Various arteries of supply to the part were in succession ligated, with the result that the oozing continued and fresh oozing from the wounds was added. After several days, transfusion of blood was employed, but it was entirely without success, and within twenty-four or thirty-six hours the patient died.

Painless Method of Treating Varicose Ulcers.

Dr. T. Will Summers writes to the *Medical Record* of a new and painless method of treating varicose ulcers. He first applies thoroughly a solution of bicarbonate of soda. After this has been done, a solution of methyl violet is applied, and it is allowed to dry. The methyl solution must be thoroughly put on, so that the base and edges are touched by it. When dry, a piece of absorbent cotton is placed on the ulcer, or, if more exist, on each one, and a Martin's rubber bandage over all. This procedure is to be repeated every morning. In the way of medication, potassium iodide in ten to fifteen grain doses, three times a day, should be administered. The author speaks of a case which recovered in six weeks, and as the bandage and internal medicine has been used with no avail, he concludes that the application of the methyl violet should be credited with some portion of the praise due for the rapid recovery.

For Amenorrhœa.

The following (*Pract.*) promises well:

Hydrargyri chloridi corrosi	gr. ¾.
Sodii arseniatis	gr. j.
Ferri sulphatis exsiccatæ	gr. xxx.
Potassii carbonatis	gr. xv.
Extracti nucis vomicæ	gr. v.

THE LIBRARY TABLE.

BOOK REVIEWS.

A SYSTEM OF LEGAL MEDICINE. Volume II.

The first volume of this work has received notice in these columns. The second and concluding volume is now before us.

All the articles are written in the light of recent research and bear the stamp of painstaking, thoughtful and accurate work.

Few better books, old or new, on legal medicine, books more valuable to the medical profession have issued from the press.

Certainly there will be differences of opinion on many subjects discussed, but this fact will not detract from the general merit of the work.

The second volume, like the first, covers a variety of subjects of great interest and value to the profession, the more important of which are:

"Duties and Responsibilities of Medical Experts."

"Insanity in Its Medico-Legal Bearings."

"Mental responsibility of the Insane in Civil Cases."

"Insanity and Crime."

"On the Relations of Mental Defect and Disease to Criminal Responsibility."

"Accident Cases."

"Mental Distress as an Element of Damage in Cases to Recover for Personal Injuries."

"Feigned Diseases of the Mind and Nervous System."

"Birth, Sex, Pregnancy and Delivery."

"Abortion and Infanticide."

"Surgical Malpractice;" and other articles of equal merit.

The work is an excellent one for both the old and the young of the profession. The second volume also contains a concise epitome of the laws of the different states which relate to the general care of the insane. Published by E. B. Treat, 5 Cooper Union, New York City. R. P.

A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. By Austin Flint, M.D., LL.D. 7th Edition. Revised by Frederick P. Henry, A.M., M.D., Philadelphia. Lea Brothers & Co. 1894.

In one respect especially does Austin Flint surpass not only the writers of his own generation but also those of our day, and that is in accuracy of description. So long as medicine continues what it still is, his work cannot be excelled. However, since his day medicine, as well as the other sciences, has been making tremendous progress, and it has been found necessary to add new material, and to describe as new diseases what were formerly regarded as being merely unusual manifestations of certain known diseases.

Here, there are new articles on Pulsating Pleurisy, Weil's Disease, Syringomyelia, Beri-Beri, Hereditary Chorea, Acromegaly, Raynaud's Disease, Leprosy, Influenza, Lithæmia, Rickets, Actinomycosis, Anthrax and Glanders.

The edition published in 1886, contained a chapter on General Pathology; this has been omitted from the present edition and Special Pathology is considered in its stead.

Instead of adopting the metric system which is now used throughout all countries, the old English system of weights and measures has been retained in prescription writing.

In spite of the additions and changes, the real charm of the old work has been maintained, and there is handed down to us clinical description, still bearing the stamp of the great writer, which will serve as standard for many a year to come. J. O.

A Case of Tobacco Deafness.

Dr. Pierre F. Spaink, of Apeldoorn, Holland, writes: "Among the poisons for the nervous acusticus, Politzer names tobacco as well as quinine, salicylic acid, morphine and chloroform. And also Dvorzak and Heinrich, who, under the auspices of Schroff, intoxicated themselves acutely by nicotine, enumerates dullness of hearing among their symptoms. The following case, in which the nervous data of the family are hemiplegia spastic infantilis of a sister and idiocy of a cousin may be of interest. J. P., aged 14, had become dull of hearing since four years; last summer he improved a little, but the next winter he deteriorated again, so that his family called him completely deaf. Inquiry learned that the left ear was nearly deaf, and the other one very dull of hearing. The membranæ tympani were normal. There was a slight catarrhus of the pharynx. No amblyopia. Sensorium intact. Pupil and patella reflexes present. Pulse without particularity. There was no loss of flesh or tremor, and all functions were normal. He smoked and chewed tobacco the whole day, so that the consumed quantity of tobacco, even at a rough guess, was not to be calculated.

"The severe presciption to use no tobacco at all, and to take much food, had the consequence that after three weeks he heard well again, which, after six weeks (February, 1894), still was confirmed. The boy, who had grown thicker meanwhile, in the beginning of May became dull of hearing again, and it was proved that he had chewed tobacco again during the last three weeks. New severe prohibition had the result that he now hears very well."—*Quarterly Journal of Inebriety.*

MEDICINE.

Cough Mixture.

Cough mixtures should be regarded as a relict of ancient and unscientific methods of practice, and as most of them do more harm than good, their employment should be relegated to well-merited oblivion

The sweeping denunciation of a time-tried, and, shall we say, fire tested remedy (?) apparently deserves some explanation, and as the season of the year is approaching when such preparations will be in active demand, some arguments against their reckless and indiscriminate use will be presented.

In the first place, cough mixtures do not benefit or improve the cough as we now understand a cough should be improved or benefited. True, the anodyne ingredient may lessen the tendency to cough, but opium or any of its preparations do harm by arresting the normal secretions, and thus the system becomes affected by the soluble poisons from the stomach and the intestine, to say nothing of the secretions retained by the kidneys, the skin, the pulmonary structures and the mucous membrane lining the upper air passages. When a person is enjoying fairly good health, he does not take cough mixtures as an agreeable pastime. No physician thinks of "bracing up" in a cold morning with a tablespoonful of cough mixture. If a man was varnished or painted all over, the elimination of poisons would be so interfered with that death would soon ensue, and this is substantially the effect that is produced by the usual cough mixture in general use. That patients who take cough mixtures do recover, will not be denied, but they recover in spite of the mixture; and it is a stubborn fact that such patients are always a considerable time in regaining their former health, simply because they suffer from the effects of toxic products taken into the circulation.

Some physicians favor a Turkish bath as a remedy for a bad cold, and in exceptional cases this plan works well; but it is not suited to many, for the reason that a bad cold is but the warning signal that the vitality of the organism has been reduced while the susceptibility to disease is increased. An able-bodied man accustomed to Turkish baths can stand one of these in case of a cold, but it is of more importance than the condition of the alimentary canal should receive the same or like attention. The danger is not all from without; it is probably greater from the alimentary tract than from the skin, and those who advocate the use of the bath, to be consistent, should at the same time insist upon the free use of a suitable saline.

In the second place, all successful (?) cough mixtures contain nauseants which tend to disorder the digestion; but were this effect is only temporary, no material harm would ensue. These nauseants, however, are now promptly eliminated, and when the patient would be in a fair way to recover, their insidious influences begin to manifest themselves, so that neither the physician nor patient can understand why convalescence is prolonged. Cough mixtures are doomed; eventually they will be damned.

In the third place, cough mixtures contain more or less saccharine substance, usually sugar in the form of sirup, originally incorporated probably to make a nauseating draught palatable; but it is now well known that the introduction of sugar into the stomach, when in an unhealthy condition, is most objectionable, inasmuch as it starts up fermentation, produces body heat, and even by the wildest stretch of the imagination has no distinctly beneficial effect upon the cough. Let us have a new regime for the winter campaign.—*Editorial in American Therapist.*

Remedy for Insect Stings.

A paint for the stings of insects, in which ammonia is kept in close and prolonged contact with the affected part is prescribed as follows:

Aq. ammoniæ.....	mcl.
Collodion.....	gi. i.
Acid salicylici.....	gr. v.

A few drops to be applied to each bite or sting.

—*Medical Chronicle.*

Pathology of Tetany.

Dr. John T. Carpenter, of Pottsville, Pa., read a paper before the American Medical Association in June last upon the above subject. After a short historical sketch, in which he credits Dance with having first noted the disease, he defines it as "a nervous disorder, evidenced by tonic spasms of an intermittent character, which may involve any or all of the groups of voluntary muscles from the extremities to the jaws, and which may be reproduced at will, during a period of intermission, by compression of the nerve trunks of great vessels which supply the muscles which have been involved in the spasm." The pathology of the condition has been almost completely unknown, mainly, perhaps from the rarity with which a fatal termination is seen, but also because of the "various forms under which it has been observed to appear, and the various conditions and circumstances which attend its development." Four forms are spoken of by the writer as having been established, viz.: (*a*) Rheumatic, or epidemic; (*b*) a chronic form, due to some debilitating condition—*e g.*, prolonged lactation; (*c*) gastric, due to dilatation of stomach: (*d*) surgical, following removal

of thyroids. The first two are very seldom fatal, whilst the last two are commonly so. Surveying the conditions under which tetany develops, we find that they present one feature in common, viz., the opportunity for septic infection. "Tetany, as a rule, follows upon such diseased conditions of the system as are observed to produce morbid discharges from mucous surfaces whose absorption is known to cause symptoms in remote parts of the body, due to the circulation of septic poison," and, summing up, "In all cases of recorded observations of morbid processes antecedent to tetany, a probable sepsis may be inferred, and no other cause common to them has, so far, been discovered. It is, therefore, logically necessary to assign the causation of tetany to this fundamental peculiarity as the antecedent factor, and to consider tetany, not as an independent disease, but as a disorder consequent upon some one of those diseases which generate septic poison."—Abstract of paper as published in *Journal of the American Medical Association.*

Tricophytosis.

In experiments Du Castel found that the following formula answered best in treating this disease:

Chrysarobin	gm 10 to 25
Salicylic acid	gm 5
Ointment of styrax	gm 5
Ichthyol	gm 5
Simple ointment	gm 5

SURGERY.

Pseudo-Puerperal Infection Due to Colon Bacillus.

From three observations by the author (Aug. Dumont, *Archives of Gynecology*) and in the clinic of M. Budin, the author concludes as follows:

1. There exists a pseudo-pueral infection of intestinal origin.

2. The etiology is the alteration of the intestinal mucous membrane from pressure of the gravid uterus, an accumulation of feces causing a stasis and infiltration of the intestinal walls. This alteration permits the colon bacilli to pass through the walls into the pertoneal cavity, causing an infection which is perhaps unrecognized under the mask of puerperal infection. The alteration consists in desquamation or roughening of intestinal mucous membrane, thereby making the advent of the bacilli easy by removing nature's barrier.

3. The symptoms vary considerable. In general, the fever appears after normal labor, followed by obstinate constipation. In ten to thirteen days the "explosion" occurs—fever 39° to 40°, pulse 120 to 130, the countenance drawn, nose pinched, the skin cold, the tongue coated, the appetite lost, and the breath fetid. Intelligence is lowered. There is pain in the region of the cæcum and the colon. Palpation may reveal a mass of considerable size, depressible, having the consistency of mastich, against the side of the uterus. By palpation the uterus may be separated from this mass. In some cases palpation reveals nothing.

Vaginal examination reveals the absolute integrity of the uterus and the cul-de-sac. The progress of the disease is variable. When there is a light infection a purgative causes the disappearance of the menancing symptoms. When the infection is profound it may continue several weeks; not infrequently ends in death.

The treatment, above all, should be prophylactic. The old custom of administering a cathartic to all patients at confinement is recommended. During pregnancy, mild laxatives or enemata should be systematically followed. On the first appearance of symptoms of this infection a brisk purgative should be promptly given. The classical intestinal antiseptics should be given; the diet, milk. Under this regime most cases recover.

Black Eye.

There is nothing to compare with the tincture or strong infusion of capsicum annum mixed with an equal bulk of mucilage or gum arabic and with the addition of a few drops of glycerin. This should be painted all over the bruised surface with a camel's hair pencil and allowed to dry on, a second or third coating being applied as soon as the first is dry. If done as soon as the injury is inflicted, this treatment will invariably prevent blackening of the bruised tissue. The same remedy has no equal in rheumatic sore or stiff neck.—*Ex.*

An Addition to the Technique of Major Amputations.

Crede (*Arch. f. Klin. Chir.*) relates his experience in twenty-two major amputations which he had done within the past two years, and in which he obtained healing by true primary union in two-thirds of the cases. In the other cases healing followed, after slight local sloughing, within three weeks, except in one case in which there had been gangrene and septic infiltration of the tissues; here healing followed after four and one-half weeks.

Contrary to the general custom, this author makes flaps composed of both skin and muscular tissues and uses neither drains nor sutures. After making the flaps and tying the arteries, he places the flaps in apposition, and holds them there by means of a moist gauze bandage, three inches wide, applied so as to exact a uniform pressure, using neither drainage tubes nor sutures. The difficulty in the method is the application of direct pressure to the surface of the stump, which he does sufficiently to hinder serous exudation and to prevent bleeding. If there chance to be points in which the skin surfaces are not in exact apposition, they heal more quickly than the tracts left by the drainage-tubes.

The method of applying the pressure is not difficult to understand. The bandage begins on the under-side of the stump, passes over the end, and is repeated until the stump is covered over; during this time the apposition of the skin edges can be observed through the thin bandage. These longitudinal turns are followed by circular ones covering in the stump; then turns, starting on the sides and passing over the end of the stump, are used, followed again by spiral turns.

The bandage remains in place from eight to ten days, when all the deeper portions will be found to have been healed. If pain or high fever show themselves, the author splits up the bandage, but does not remove it, covering it in with another bandage.

Treatment of Artificial Anus.

Chaput (*Archiv. Gen. de Med.*) records thirty-five cases of artificial anus and stercoral fistulæ which he has treated. After an exhaustive survey of these cases he has formulated the following conclusions concerning the treatment of this class of cases: He says that artificial anus can be treated by four different methods: (1) By the application of enterotomy, followed by obliteration of the fistula. (*a*) Enterotomy is indicated when the cases are uncomplicated and the aperture is easily accessible, together with a thin and long partition. When the spur is long and thin it is advisable to adopt Richelot's method, that is, section between two pairs of forceps and immediate suture. If, however, the spur is long and somewhat thickened, it is better to make the suture between to long pairs of forceps, which are allowed to remain in position. Enterotomy is contra-indicated when the spur is very thick or inaccessible, or when the aperture is closed by the mechanism of angular wounds. (*b*) After destruction of the spur, the stercoal fistula is closed. Small fistulæ are closed by lateral enterorrhaphy, during which operation the margins of the fistula are freely separated from their surroundings, and then united with two tiers of sutures, the peritoneum being opened or not according to the requirements of each individual case. In the case of large fistulæ lateral enterorrhaphy may be emyloyed, but the peritoneum should not be opened. (2) Resection is as a general rule contra-indicated, but when in the course of a lateral enterorrhaphy the intestine is easily friable and is largely lacerated it is necessary to resect the two ends and reunite them by appropriate sutures. (3) Longitudinal enterorrhaphy: When the enterotomy is for some reason contra-indicated, it is sometimes advisable to employ longitudinal enterorrhaphy without resection. This operation is done by making a circular incision in the skin around the artificial anus and opening the peritoneal cavity. The two ends are drawn out, a longitudinal slit is made in each, and then the margins of the slits of the same side are sewn together with sutures. This operation is indicated when in the course of a lateral enterorrhaphy considerable constriction is met with just below the lower end. When the intestine is very friable it is contra-indicated. (4) Entero anastomosis: Entero-anastomosis, followed by ligature of the two ends between the point of anastomosis and the stercoral aperture, is a simple, easy, and benigh operation. It is indicated when the intestine is very friable at the seat of the artificial anus, or when there is a considerable constriction of the bowel in the neighborhood of the external aperture, and also when the inferior end is obliterated at the level of the artificial anus.

Treatment of Spasmodic Torticollis.

In discussing the operative treatment of spasmodic torticollis, in the *American Journal of the Medical Sciences*, Drs. Maurice B. Richardson and George L. Walton, of Boston, draw the following conclusions:

1. Palliative treatment, whether by drugs, apparatus, or electricity, will rarely prove successful in well-established spasmodic torticollis.
2. Massage may prove of value in comparatively recent cases.
3. Resection affords practically the only rational remedy.
4. Operation on the spinal accessory nerve may afford relief, even if other muscles than the sterno-cleido-mastoid are affected; on the other hand, the affection previously limited to the sterno-cleido-mastoid may spread to other muscles in spite of this operation.
5. No fear of disabling paralysis need deter us from recommending operation, as the head can be held erect even after the most extensive resection.
6. The most common combination of spasm is that involving the sterno-mastoid on one side and the posterior rotators on the other, the head being held in the position of sterno-mastoid spasm with the addition of retraction through the greater power of the posterior rotators.
7. It seems advisable in most cases to give preferenoe to the resection of the spinal accessory as the preliminary procedure.

Ichthyol in Fissures of the Anus.

Van der Willigen warmly commends ichthyol in the treatment of fissures of the anus (*Journ. de Med. Monatshefte fur Praktische Dermatol*). The pure drug is introduced into the anus by a brush. The contraction of the sphincter forces this into all the folds of the mucous membrane. Little pain is excited. Treatment should be repeated daily. This patient is given liquid diet and occasionally castor oil. The first patient, who had previously been treated by every means short of operation, was cured in eight days, the other three in two or three weeks. One had already been subjected to operation without benefit. There was no recurrence.

OBSTETRICS.

On the Treatment of Abortion by the General Practitioner.

After a discussion of the causes and diagnosis of abortion, the prophylactic treatment is outlined. Underlying causes, in which are especially mentioned chlorosis, abnormal fixation and laceration of the cervix, indicate the direction in which therapy should be applied.

Unavoidable abortions may be considered in three classes:

1. As beginning abortions. If the process be not spontaneously accomplished the placing of a tampon is indicated, and if necessary the manual removal of the fœtus.

2. As incomplete abortions. Here the removal of placenta and membrane should be thoroughly accomplished with the finger introduced sufficiently high in the uterus to sweep the whole wall. The use of instruments is not indicated. Dilatation of the cervix may be accomplished by introducing within it gauze that shall act as a tampon, and the subsequent employment of Hegar's dilators. If the os is patulous, narcosis is not necessary.

3. Complete abortions followed by hemorrhage. Here commonly the dull curette is to be used, but not always necessarily. On the contrary, a dietetic treatment with the use of the proper drug—ergotin—will not infrequently suffice.

After every operation an antiseptic, intrauterine douche is demanded, and so much the more if there be fever.—*Dr. Czanpin. (Berlin: Boas and Hesse).*

Cold Bathing During Menstruation.

Cold bathing during menstruation is a beneficial measure, provided women accustom themselves to the treatment by bathing every day for at least eight days before the arrival of the period, when they can continue during the menstrual flow without any danger. In the case of a very anæmic girl in whom this treatment was instituted it gave most satisfactory results. Houzel, before the recent Boulogne Congress, held that cold salt-water baths facilitate the menstrual flow, increase the duration of genital life, and likewise increase fecundity in a remarkable manner.—*Doctor Depasse, in Gazette de Gynecologie.*

Photographing the Womb.

A swiss physician has described a method of dilating the uterus by means of tents, so that by the use of a mirror a perfect view may be obtained of the interior of the organ. Not content with this, however, he is unselfish enough to desire to obtain photographs of the uterine interior in various diseases of the organ. The future of woman is sad indeed if now her womb must not only be felt of, sounded and measured, but photographed as well.—New York *Polyclinic.*

Pigmentation in Amenorrhœa.

Lawrence (Bristol *Medico-Chirurgical Jour.*) reports the case of a girl suffering from amenorrhœa with pigmentation. This became so marked as to suggest Addison's disease. She was treated with wine of iron, 1 drachm, and Fowler's solution of arsenic twice daily, burgundy in moderation, careful diet, the addition of milk, and her life regulated in accordance with general hygienic principles. This resulted in complete cure after many months.

The Decline of the Pressary.

The *Lancet Clinic* says editorially: "No one invents a pressary nowadays in strange contrast to the time when scarcely a man prominent in the practice of diseases of women did invent one." One may conclude from this that either all available pessary devices have been invented or that the use of the pessary is to be discouraged.

It is the latter view that Dr. J. G. Blake holds in a communication of the Obstetrical Society of Boston, April, 1894; his alternative for the pessary is of course surgical procedure. His complaint is more of the abuse than the use of the pessary, although he quotes Fritsch, a German writer who declared that he had spent ten years in learning the treatment by pessaries and considered it the most difficult in the whole range of gynecology, and that it is ealser to perform a laparotomy than to apply an accurately fitting pessary.

The same author criticises their use, declaring that the pessary heals palliatively, but injuries definitively; for it distends the fornix vagina so enormously, that even after it has been worn for years, a cure is not to be hoped for. On the contrary, retroflexion of the uterus returns after the removal of the pessary. The longer the uterus has been displaced the longer the time necessary to enable the reflexed ligaments to return to a normal condition; and a few days have been sufficient after its withdrawal to have the uterus fall back into its old position.

Among the means for obtaining permanent cures, Blake mentions narrowing the vagina; pregnancy following by prolonged rest in bed; dilating and curetting; and shorteneng the round ligaments. The first, he says, is only called for in complete prolapse, where no instrument, without external support, will keep the uterus within the vagina, but where it can be accomplished by narrowing the canal and the outlet; these cases are comparatively rare. The operation of dilating, curetting and packing is particularly adapted to the cure of anteflexions, and to the removal of enlargements which attend all forms of backward displacement. The combined dilating, curetting, and Alexander, is to his mind, the true solution up to date of the vexed problem of backward displacements.

Ventral fixation, by opening the abdomen, and by various other methods (the vaginal, for instance) of fastening the uterus, had

been advocated by many writers. He sees no advantage in them over the simple, harmless and in most cases effective operation in proper cases, and of dispensing with pessaries.

He thinks no one has yet devised a simpler, less dangerous or more effective measure for the emancipation of women from the wearing of pessaries than the two operations of dilating and curetting, and Alexander.

[In spite of the craze for operating, a skillfully adjusted pessary serves an excellent purpose in some cases.—*Ed.*] *Western Med. Reporter.*

Profuse Menstruation.

The Canada Lancet contains an able article on this subject by Dr. Charles P. Noble, who, after a thorough discussion, offers the following:

Conclusions:—1. Menorrhagia is young virgins is usually functional, due to disturbances in the vaso-motor nervous system or to relaxation of the tissues, in general caused by the rapid growth which at times takes place about the time of puberty. Because of its pathology menorrhagia in young virgins is usually curable by general treatment.

2. Menorrhagia occurring in young childbearing women is usually due to some mishap in connection with pregnancy or parturition, such as the retention of products of conception, laceration of the cervix or perineum, retro-displacement of the uterus, sub-involution, inflammation of the uterine appendages, and pelvic congestion. Menorrhagia in this class of women is curable. It usually requires local treatment of an operative nature. When due to sub-involution and malpositions of the womb, operation is unnecessary.

3. Menorrhagia in women approaching the forties, and in those who are older, is usually due to gross diseases of the uterus, such as fibroid tumors, polypi, adenoma, or malignant tumors. Menorrhagia occurring in this class of women, except when due to advanced malignant disease, is curable, but almost invariably requires operative treatment applicable to the disease present in the particular case.

4. As memorrhagia is a symptom and not a disease, an exact diagnosis is requisite in every case. With the exception of young virgins it is desirable that a physical examination of the pelvic organs be promptly made. The importance of this examination is the greater with the increasing age of the patient. Special considerations should influence the practitioner to postpone the local examination in the unmarried, unless it be reasonably certain from the symptoms that gross local disease is present.

5. There is no treatment for menorrhagia *per se*. By general measures, such as rest in bed and the use of digitalis and strychnine and ergotine, pelvic congestion can be lessened, and in that way menorrhagia can be, at least in part, controlled; but it cannot be too strongly insisted upon that in every case of menorrhagia an exact diagnosis must be made, and the appropriate treatment addressed to the disease which is present.

DISEASES OF THE NOSE.

Zinc Sterate in the Treatment of Atrophic Rhinitis.

The author, Dr. Joseph F. Gibb, discusses the nature and general management of atrophic rhinitis, and concludes by outlining the treatment pursued at the Episcopal Hospital of Philadelphia, and the results obtained in fifty four carefully selected cases. The plan of treatment consisted of cleansing sprays, followed by stimulating applications, as usually recommended in the management of atrophic troubles. The cleansing was accomplished by spraying the nostrils with an antiseptic detergent solution (Dobell's Solution), followed by applications of a hydrogen peroxide on a cotton wrapped probe if the inspissated crusts were not otherwise removed. After the membranes were entirely free from secretions they were coated with a thin layer of powdered sterate of zinc containing 25 per cent. of europhen applied by meanns of a powder-blower.

Stearate of zinc has an oily feel when handled and has a peculiarly strong adhesiveness to mucous surfaces, thus exerting an influence for a prolonged period when applied to mucous surfaces. The drug produces an unpleasant effect when used in the nose, and nearly all patients claim that its use is very agreeable. Very satisfactory results were obtained in the cases treated at the Episcopal Hospital, three or four treatments in some instances being sufficient to eliminate the disagreeable odor as well as the formation of scabs. The patients were treated twice per week, and in the internal between treatments were instructed to use a cleansing solution made from Seiler's Tablets. In a total of thirty-two cases of atrophic rhinitis that remained under observation until discharged, the shortest time being two months, the longest eighteen months, there were twenty-seven in which there was a complete disappearance of crusts and odor. The author concludes by recommending sterate of zinc as a base for carrying stimulating applications, because of its simplicity of application, its effectiveness in relieving the distressing symptoms, and the comfort that it seems to induce.

ORIGINAL ARTICLES.

ANGIO-SCLEROSIS.*

CHARLES CARY, M.D.,† BUFFALO, N. Y.

This first patient appears before you, not because he shows an active condition of disease at present, but because he is one of a group of cases that I propose to present to you—a group manifesting very different symptoms, but all dependent on one and the same trouble, a vascular disease which we may term angio-sclerosis.

Various parts of the circulatory system may be involved. In one phase of the disease the veins alone are affected; in another the arteries and heart; in a third the arteries, veins and capillaries. The primary cause is often a toxic element, particularly that of syphilis or of alcohol. There is no typical clinical picture of the disease for the reason that the lesions are dependent upon the particular set of vessels involved. Thus the predominant symptoms may be referred to the brain, if the cerebral vessels are involved; gangrene may develop if there is absolute occlusion of an artery in a limb; and as the different cases are brought before you, you will see other phases of the same general condition.

I.—The history of the first patient is as follows: "W. P., aged fifty, family history good; is a hard drinker. He had a chancre followed by a universal eruption twenty-three years ago; took medicine for two months and has never had specific medification since. Ten years ago he had a sluggish ulcer over the hip, which persisted for a long time. Five weeks ago (eleven weeks prior to clinic) a small sore began on the posterior surface of the left leg."

On admission to the hospital the patient had a ragged, deep, indurated, indolent ulcer over the calf of the left leg. The leg was thickened and œdematous, not with the œdema of renal disease which is soft and pits easily on pressure, but with a tough, leathery induration and infiltration of the tissues. On the right leg, though there is no ulcer, you can see a bunch of distended veins which feels like a lot of angle worms under the skin. With the slight obstruction of the return circulation made by rolling up his trousers, the superficial veins are rapidly enlarging. You can readily understand that with veins so lacking in proper tone as these, the constant obstacle to the return of blood occasioned by gravity alone is sufficient to cause a bursting of some branch, a diminished withdrawal of effete products from some area, and, consequently, an ulcer which does not tend to heal spontaneously and which may resist all our efforts to effect a cure.

* Clinical lecture delivered at the Buffalo General Hospital.

† Professor of Materia Medica and Therapeutics, University of Buffalo.

There is no condition which will offer so great an opportunity for the establishment of a reputation, as some phase of angio-sclerosis that is amenable to treatment. One may be able to heal an ulcer that has persisted for years; and, as you will see in some of the cases to be brought before you, it is possible to bring a man from an apparently dying condition to one of comfort and relative health. At the same time it is rarely possible to effect a radical cure, and many cases of chronic ulcer will prove obstinate.

This patient was put upon his back, with the leg elevated so that gravity would assist the return circulation so far as possible. An elastic bandage was put around the leg to cause the resorption of the old exudate, and a very simple ointment was applied to the ulcer. I was rather interested to determine whether there was anything of a syphilitic nature about the sore itself, as there undoubtedly was about the underlying condition of vascular degeneration. With this question in view, I suspended the potassium iodid that he had taken only for a day or two, so that there should be no indirect help in the healing of the ulcer. He was given nutritious diet and an occasional dose of Carlsbad salt to aid in the elimination of resorbed products. The improvement is evident to all who can compare his present condition with that of the time of admission to the hospital.

The underlying cause of his arterial and venous changes must be looked after. Alcohol must be interdicted, the occupation should be such as will not keep the patient upon his feet too much of the day, and especially not unless he can walk about, for standing still is worse than walking, since muscular contraction and relaxation aid in the onward flow of blood through the veins. It would also be well for the man to wear constantly on both legs elastic stockings. These should come up above the knees, for I find that the popliteal veins are very noticeably involved in the dilatation. Potassium iodid would be indicated for the purpose of opposing the tendency toward deposition of occluding connective tissue in the intima of the vessels.

II.—The second patient entered the hospital three weeks ago, and I am sure I do not overrate his condition when I say that he was not expected to live twenty-four hours. He was cyanotic, even his nails were blue; his eyes started from their sockets; he was gasping for breath, and unable to gain the necessary amount of oxygen though his respirations were thirty or more to the minute. His temperature was 100° F., soon dropping to 97°; the pulse was 125 and extremely weak. There was an almost uniform edema of both lungs, and, on account of this condition, the liver was pressed downward about two inches. There was nothing in the family nor previous personal history of the patient to explain his condition. A year ago he had a somewhat similar attack, during which swelling of the feet and shortness of breath were noticed. His present trouble began three weeks ago in the same way, and the shortness of breath is directly accounted for by the edema of the lungs, while the edema, both of the lungs and of the extremities, is to be referred to the circulatory disturbance. To-day, the patient walks into the clinic and says that he feels as well as usual. Yet, while you might not at first sight recognize him as a sick man, you should be able to diagnose his fundamental condition even in the present state.

Arterial sclerosis is a degenerative disease primarily, but the degeneration is followed by an inflammation, and the two processes thenceforth go on hand in hand. A marked thickening of the internal coat of the arteries is caused, producing more or less obstruction. Then there comes a breaking down of the newly formed tissue, with points of necrosis and, later, the deposition of calcareous matter in these points of necrosis, so that the wall of the artery becomes rigid, irregular and as hard, almost, as pipe-stem. Save for the irregularities, the comparison to a pipe-stem in this case would be a good one. Very similar changes may occur in the veins, and I shall never forget a case that was sent to the hospital two years ago by Dr. Benedict. The patient was an old woman whose veins were so calcified that, by rapping on them with a pencil, I could elicit a sound loud enough to be heard all over the room.

According as the change occurs in arteries, veins, capillaries, or heart, one or several combined, and as different parts of the body are involved, various symptoms are produced. Thus, the varicose ulcer

and the stroke of apoplexy are due to the same underlying cause—the latter representing the cerebral type; while we may also recognize cardio-vascular sclerosis, a renal type, and a combination of the latter two in the so-called arterio-capillary fibrosis.

Angio-sclerosis is usually a manifestation of age and yet of age which cannot be measured by years. Some people bring about these changes in their arteries from abuse or overuse, and there is not the least doubt but that some are older at twenty-nine then are others at sixty. The duration of the youthful state of the arteries depends largely on heredity, upon the amount of elasticity of the vessels, upon the longevity of the family. The poisons of infectious diseases are a curative factor, and among the very worst and youngest cases are those dependent on syphilis. Syphilis may produce absolute obliteration of arteries and, thus, gangrene.

You will notice that this man has a very tortuous temporal artery. On attempting to feel the pulse in the left wrist, I come upon what feels like a lymph-node. In the right wrist, the artery makes a backward turn, and as I run my finger along it, it has the rough feeling of the trachea of a bird. Such an artery is often likened to a string of beads. I can feel the artery three inches above the wrist, where it never should be felt, though we may in a lean person feel the beat of the pulse as far as that. There is a difference between feeling an artery and feeling the pulsation of blood through it.

The examination of the heart should verify the diagnosis by an increase in the aortic sound, indicating a resistance to the outward passage of blood from the arteries. The heart-sounds, now, are not abnormal, but when he entered the hospital the first sound was scarcely appreciable, the rhythm of the beat was lost, the action of the heart was reduplicated, intermittent and irregular. There were no murmurs, but there was an exaggerated second sound both over the aortic valves and over the pulmonary artery, since the edema of the lungs as well as of other parts interfered with the onward rush of arterial blood. I believe that the patient has still a congested liver. The upper border is at the fourth rib, where the nipple is located, but the lower margin is an inch below the costal arch.

What was done to relieve the patient? His arterial tension was diminished by doses of glonoin, measured not by the amount but by the effect. Some patients will take only $\frac{1}{100}$ grain, two or three times a day; others will require $\frac{1}{50}$ every hour, and if $\frac{1}{50}$ will not accomplish the desired result, give $\frac{1}{25}$. The very tolerance shows that there is great need of the drug. There was also promptly given a saturated solution of salts with the object of depleting the portal system which, at that time, was overloaded with blood and was giving rise to hepatic congestion. I believe that the general edema of the lower extremities was due in great measure to the portal obstruction and not to the condition of the general circulation. The patient was kept on his back to lessen the work of the heart, and, in spite of the need of depressing blood tension, there was also an indication for stimulating the heart, which was done by the administration of small doses of digitalis. Once the patient was cupped, but I will say that this procedure probably did not relieve him. When you apply cups, you bring about a local congestion and edema, and this is useful in withdrawing blood from an inflammatory process. It is said that you can make an actual imprint upon the pleura, so that there is a possible contra-indication to the use of cups in pleurisy. The way to help along a laboring heart, is not to draw blood into any part of the venous circulation which is already overloaded with blood, but to hurry the blood onward. Thus, cardiac stimulants, vaso-dilators and hydrogogue cathartics are indicated. Under this treatment the heart regained its regularity and the patient feels quite well.

The only sample of urine of which a quantitative examination was made, amounted to 400 c.c. for the 24 hours; was red, acid; of a specific gravity of 1035; contained 12 grams of urea, a small amount of albumin, but no sugar. The microscopical examination was negative. Albumin was found in two of three samples examined.

In almost all these cases there are, sooner or later, renal changes. When the circulation is of such a character renal complication is inevitable if the disease lasts long enough. The degeneration progresses gradually from the other vessels to those of kidney, so that, finally, a

granular kidney results. When there is marked involvement of the kidneys and the urine is scanty, the steam-bath becomes a very useful addition to the treatment, as it calls the skin to our aid in eliminating the waste products which the kidneys can not dispose of.

The question is asked whether bleeding would be indicated to relieve arterial tension. Personally, I do not indulge much in bleeding, though it is undoubtedly an excellent procedure in certain cases. In cases such as this, it would be useful to let off blood in the far or venous side of the circulation, and yet we must consider that the patient is not in a condition to actually lose blood. Though he has too much in his veins, he has not too much, and perhaps not enough, in his whole circulation. Particularly when the pulse is hard and bounding, I have resorted to a substitute for bleeding-profuse purgation. Such a course is indicated when an apoplexy is threatening. You will come upon cases in which one stroke of apoplexy has occurred and the patient has a hard, bounding pulse and sensations of vertigo, and in these circumstances, prompt blood letting is undoubtedly of benefit; yet you can not prove that you have averted a stroke of apoplexy. If there is already a cerebral hemorrhage going on, it may be imperative to diminish blood pressure at once by venesection, but under ordinary circumstances the few hours' delay in bringing about the same end by purgation will be immaterial.

III.—The history of this patient is as follows: "Aged fifty-four, Irish, laborer, single, family history good, moderate drinker up to six years ago, has had gonorrhœa and syphilis; syphilitic eruption in 1864 removed by treatment, recurred a year later and lasted four months, after another course of treatment the eruption disappeared finally. Four months ago had retention of urine, being able to pass only the overflow. Two weeks ago, took cold and suffered with pains in bones and some fever. Appetite poor, bowels constipated, great thirst most of the time."

This patient has not come in here with any active disease; he expresses himself as feeling "mean." He has no real pain but a general soreness, and though he can walk, he becomes easily fatigued. He has some headache, for the most part frontal.

He is rather a robust man, his skin is aged not more than 54, but his arteries are at least 90. They have nearly run their course. His pulse is slow, but the heart itself is not particularly involved; certainly not in the sense that there is a well marked valvular disease or alteration in size. Sooner or later, however, the heart, acting against unyielding pipe-stem arteries, will dilate. The arterial changes are most marked around the coronary arteries in many cases, and these vessels may become partially obliterated. In that case, the heart will receive a diminished blood supply, a fibrosis and fatty degeneration will occur, and a cardiac dilatation with all its symptoms is inevitably added to the type of arterial sclerosis. Usually, such dilatation causes a disproportion between the valves and their openings, so that regurgitation results. Sometimes the coronary arteries become plugged and death follows immediately. This man's aorta would undoubtedly present an ulcerated surface with thick calcareous scales. These may become detached and form emboli wherever they happen to lodge.

The question is asked whether such a patient, with a good heart and degenerated arteries, is not especially predisposed to aneurysm. The point is very well taken, and yet a tabulated list of these cases will show that aneurysm comes much earlier in the course of the disease, usually being developed by the fortieth year. It may be that although the circulatory organs predispose to the occurrence of some lesion, the brittleness of the arterial coats prevents the gradual yielding that is necessary to the formation of an aneurysm.

I believe that the arteritis in this case is syphilitic. It can scarcely be ascribed to heredity; his mother lived to the age of 85, and his father was carried off suddenly at 55, by inflammation of the bowels. In a patient who seems to be otherwise well, with arterial sclerosis so well advanced and without a marked family tendency, the probability is that the lesion is syphilitic.

Alcohol should be avoided. Antisyphilitic treatment should be continued vigorously and for some time. Potassium iodid seems most suited to this stage of the disease, but even here small doses of mercurous iodid may be added with advantage. I would give a very liberal allowance of liquids. Milk is easily digested

and, at the same time, it will aid elimination and will be unirritating to the kidneys. Derivatives are not indicated as a routine, but the tongue is coated and, more on account of the condition of the stomach than for the sake of causing elimination through the bowels, I would recommend the administration of Carlsbad salt. At times, I would stop the mercury and replace it with iron. The amount of change that these arteries have already undergone will not be materially modified. It is as much of a permanent change as would be a scar on the surface of the body.

IV.—The most marked case of angiosclerosis that we have in the hospital at present, is that of a man who was brought here with the expectation that he would die in the ambulance. He illustrates rather the cerebral type of the disease. He is a little rebellious; somewhat inclined to be talkative, though, at other times he is dull; his memory has failed markedly, and he presents various other signs of mental alienation. There is considerable albuminuria, and this morning he does not seem to have clear vision, since he says that he can see only a few persons present, and has to turn his head little by little to take in a view of the clinic room. He explains that he has not cleaned his eyes this morning, but there is no gumming of the lids. You will notice the peculiar pallor of the hands and extremities in general, and the puffiness under the eyes. These are at present the only indications of the renal complication of the general condition. When he entered the hospital he had pulmonary edema to such a degree that his respirations were above 30 to the minute for several days, and on one occasion reached a frequency of 48. The line of treatment was exactly the same as for the second patient studied.

This patient will probably recover sufficiently to leave the hospital, but he will not improve to any marked degree. Evidently parts of his brain are insufficiently supplied with blood, and we should rather expect those degenerative changes to occur which have been called softening of the brain—the term is not a good one. Without showing the signs of apoplexy, the case is, nevertheless, one that comes under the category of cerebral angio sclerosis.

BENIGN TUMORS OF THE LARYNX; REPORT OF A CASE.

DUNBAR ROY, A.B., M.D., ATLANTA, GA.*

According to my observation tumors of the larynx, whether benign or malignant, are by no means so common in America as they are in European countries. Whether this be due to external influences, habits of living, or to some racial peculiarity I am unable to say, but these observations of mine are in accord with those other writers upon this subject.

The importance of any disease is never more forcibly impressed upon the public than when it has attacked some potentate or person of eminence; hence it is that since the time when the Emperor of Germany fell victim to the ravages of an endolaryngeal neoplasm, laymen and physicians have viewed with awe and gloomy prognostications the final outcome of any laryngeal growths.

Long before Emanuel Garcia gave to the world the now invaluable laryngoscope, tumors of the larynx were diagnosed by palpation and ausculation. Morel McKenzie tells us that Koderik operated successfully upon a growth through the mouth about the year 1750, it being perhaps the first authentic case on record. From that time on, various uncertain cases were reported, but it was not until 1850 that Ehrman published in Strassburg his celebrated treatise on that subject with a report of thirty-one cases. In 1852, a still further addition to the list was made by Dr. Horace Green, of New York, who reported fifty-two cases, among which two had occurred in his own prac-

*Professor of Ophthalmology and Otology in the Southern Medical College, Atlanta, Ga.

tice. While the report of these cases had all been of interest, they had been found mostly at post-mortem examinations. By the invention of the laryngoscope new impetus was given to the subject and soon the list was augmented by the report of additional cases. In 1866, among the very first, was a monograph by Dr. Elsberg, of Philadelphia, in which he reviewed the subject and reported thirteen cases of his own. Since then, cases have been recorded, especially by Morel McKenzie of London, Stoerk and Schmitzler of Vienna, Oertel of Munich, and, in 1876, Fanvel, of Paris, reported three hundred cases with two hundred and twenty operations. Fanvel was among the first to introduce instruments for the successful removal of these growths through the mouth. An excellent work was published by Dr. Paul Bruns in 1878, on the relative merits of endolaryngeal treatment and throtomy. Since that time so many cases have been reported that, now, they are no longer looked upon as a rarity. One case occurring in my private practice, is of enough interest to allow some practical points to be deduced.

H. M., German, aged twenty-five, baker, presented himself at my office on account of hoarseness which was gradually increasing. The patient is strong, healthy-looking, and gives no external signs of disease. Says that he has always enjoyed good health, the only trouble being with his throat, with which he has suffered for the last two years. He suffers a great deal with colds, at which times his throat-trouble is much more irritating. He has been hoarse now for two years, but beyond that there is no uncomfortable symptom. His breathing is never interfered with.

No trouble was experienced in getting a good laryngoscopic picture. Anteriorly on the free and lower border of the left vocal chord, there could be seen a little polypoid mass about 6 mm. broad. It was not pedunculated, a portion of it protruding above the vocal chords on attempted phonation. With a probe the mass was found to be freely movable, and it bled but slightly from such manipulations. A diagnosis of papilloma was made clinically, which was afterwards confirmed by the microscope. The vocal bands and sides of the ventricles were partly covered with a thick, dirty secretion. The mucous membrane appeared atrophic, and this condition extended up the pharyngeal wall into the nasal cavity, On examining the nose a marked case of atrophic rhinitis was seen, with large flakes of dirty yellowish secretion clinging to its walls. It was very evident that this secretion was exaggerating the condition which already existed in the larynx.

As a laryngeal image could be perfectly obtained, there was no necessity for training the parts in order to carry out the instrumental manipulations which were to follow. The tumor was removed without much difficulty with a pair of laryngeal cutting forceps. At the point of removal the chord was very much thickened and parts of the basal attachment of the tumor remained. These latter I removed with astringent applications of chloride of zinc and the electro-cautery. From this time the voice was much louder and clearer, the only trouble being a slight degree of hoarseness in the morning, due to the clogging up of the larynx during the night with the sticky atrophic secretion.

Tumors of the larynx are divided, like tumors in other portions of the human economy, into (1) benign; (2) malignant. Fortunately for the human race the latter class is very rare, and since the case reported comes under the head of benign, my few remarks will be confined to that class.

As to the cause of these benign growths many writers differ. Sir Morel McKenzie holds that chronic congestion of the laryngeal mucous membrane is the most prolific cause of these growths, and, since a catarrhal condition of the nose and throat is a leading factor in this chronic congestion, it must be looked upon as a most decided predisposing cause. In like manner many writers hold that a chronic catarrh of the nasal mucous membrane is the main causal factor in producing the different growths in that locality—polypi, fibrous excrescences, exostoses, etc., and some of them go so far as to say that it is the only cause. Lennox Browne is another writer who believes in local irritation as the exciting cause. He quotes McKenzie as saying "that diathetic conditions, as syphilis, tubercle, etc., exercise a decidedly antagonistic influence to the development of new formation," which Browne strenuously denies and cites several cases as sustaining him in these views. Cohen

believes that the exanthemata, variola, scarlatina, etc., through the catarrhal condition which they occasion upon the respiratory mucous membrane, are frequently exciting causes. McKenzie says that the professional use of the voice is one of the circumstances favorable to the development of these growths, and declares that 21 per cent. of his patients old enough to have such an occupation, were subject to this influence. Strange to say, in this statement there is unanimity between him and Lennox Browne, and both of them have had large opportunities for examining the throats of professional vocalists.

As to the age in which these growths most frequently occur, there appears, as usual, a diversity of opinion. Dr. Tabold in his article "Die Chronischen Kehlkopfskrankheiten," says that the affection is most common in middle life, from the thirtieth to the sixtieth year; that laryngeal polypi are least frequently seen in childhood. Dr. Causit, on the other hand, believes that they most frequently occur in early infancy, and goes so far as to say that the disease is very often congental. Dr. Arthur Edis has reported (*Transactions of the Obstetrical Society of the United Kingdom*), the case of a child who died from suffocation thirty seven hours after birth, and a cyst about the size of a hazel nut was found in the larynx. Dr. McKenzie, from the statistics of cases treated by himself, concludes that the most favorable time of life is between the ages of twenty-five and fifty. Doctor Burns has reported a case of tumor in a patient seventy-four years of age, while Rosenbach has reported 86 operations for laryngeal polypi, the youngest being four and a half years old, the oldest between sixty and seventy.

Benign tumors of the larynx are divided by most writers into the following classification:

1. Papillomata.
2. Fibromata.
3. Myxomata.
4. Cystic tumors.
5. Angiomata.
6. Lipomata.

Of these the papillomata are by far the most common, and such was the character of the neoplasm reported by me. McKenzie says, "In my one hundred tabulated cases, sixty-seven were judged to be of this character." It would be impossible for me in this short article to go into the clinical characteristics of all the benign neoplasms, and since the case reported above concerned only a papilloma, my remarks will be confined in the main to this class, both in regard to symptoms and treatment.

Papillomata of the larynx may be either sessile or pedunculated, and while they usually occur singly, they may be multiple in their growth. They are usually small and are by no means limited to one special position, although Lennox Browne says that they occur most frequently in the anterior portion of the vocal chords, and on the right more frequently than on the left. They are usually of a pinkish color and, according to Browne, they do not bleed easily when touched with a probe, which is one of their diagnostic points.

The symptoms to which they give rise depend largely upon their size and position in the larynx. For instance, growths upon the epiglottis will occasion some discomfort upon deglutition, while those upon vocal chords will have aphonia as their most prominent symptom. Aphonia is, perhaps, the most prominent symptom, since the vocal bands are more often the seat of origin for these growths than any other point in the larynx, Another noticeable fact, which has been mentioned by various writers, is that a small growth is more apt to produce aphonia than is a large one, since the latter sometimes takes the place of a true vocal cord in the patient's effort to articulate. In the patient referred to, hoarseness was one of the prominent symptoms, and in fact the only one. He had been treated with all the remedies known to materia medica, both by internal administrations and by inhalations, with, of course, no beneficial results. And right here I should like to call attention to the fact that general practitioners are not as familiar with the use of the laryngoscope as they should be —knowledge which requires but a small outlay for the necessary instruments and but very little practice for the proper manipulation of the same. Cases other than mine, are frequently reported, where hoarseness and the other symptoms of chronic laryngitis have been treated for years with the ordinary remedies, to be relieved finally only by the removal of a laryngeal growth which was found to exist.

The treatment of papillomata is their removal as thoroughly as possible. I say

possible, meaning of course their removal through the mouth, for whenever they are so large as to render it impossible to remove them in this manner, their size will very probably soon demand a laryngotomy. These neoplasms not being primarily malignant, are injurious mainly in their interference with phonation and the chances of their becoming so large as to interfere with respiration. When not excesively large their removal through the mouth is usually not very difficult; yet this operation, like many others, requires considerable dexterity on the part of the operator. Various instruments have been devised for the removal of the growths, in the way of cutting forceps, laryngeal knives, snares, etc., but I have found that the most satisfactory instrument is the Gibb's laryngeal écraseur. I believe with Lennox Browne, that every instrument capable of doing injury to the larynx should be thoroughly guarded. The cold wire snare is the least dangerous to the parts and when rightly manipulated is most satisfactory in its results. Cutting forceps, as a rule remove only a small portion of the growth at a time, and that usually with a good deal of pulling and tearing, and with much discomfort to the patient. Prof. Storck's cutting instruments are of course free from these objectionable features. Dr. McCoy, of Philadelphia, extols the galvano-cautery for the destruction of the growths, but any one who has ever tried to use a cautery point in the larynx knows how apt this organ is to contract at the wrong moment and in this way receive irreparable injury. In the majority of cases, even with the use of cocaine, the patient must be trained for a week or two before he or she will endure instrumental manipulations in the larynx. Some laryngologists use strong chemical caustics to destroy these neoplasms, but such procedures are obsolete, and are entirely too tedious if the tumors are large enough to be grasped by instruments.

The question has often been asked whether these benign growths are not apt to be transformed into those of a malignant type, especially if there is instrumental interference. In answer to this question, I can do no better than recite the ideas of the late Sir Morel McKenzie on the point. He says that beyond the recurrence of the neoplasm at the point of removal, he knows, in his own experience, of no case which has subsequently taken on a malignant type from laryngeal irritation. In the literature upon the subject, he knows of but three authentically reported cases.

To sum up in a few words the main points brought forward on this article:

1. Neoplasms of the larynx are either (*a*) benign, or (*b*) malignant.
2. Of the benign growths, papillomata are by far the most frequent, and, as a rule, occur between the ages of twenty-five and fifty.
3. The main symptoms are (*a*) aphonia, (*b*) dysphagia, (*c*) dyspnœa.
4. The best treatment is their removal whenever possible.
5. The best authorities agree that a transformation into the malignant type from instrumental interference does not occur.

The Chemical Pathology of Uræmia.

In a recent experimental study of uræmia, Hughes and Carter have contributed to the pathology of this important condition (*Amer. Jour. of the Med. Sciences*). They conclude that there is one poison, present alike in uræmic human blood, in dropsical effusions in uræmia, and in dog's blood in experimental uræmia; and that this poison is not one of the ordinarily recognized constituents of the urine, as generally believed, but one whose nature or even existence has not before been recognized. The facts that its action is much lessened after subjection to moderate heat, and that it is not readily dialyzable, seem to indicate that the poison is an albuminous body; while clinical evidence indicates that it is not a constant constituent of the blood, but produces the uræmic condition by accumulation, owing to the inability of the kidneys to excrete it, or more rarely by a sudden and enormous production. The order in which serums stand as to their toxicity, proceeding from the most toxic to the least, is, man's, the dog's, the horse's. This suggests to the writers that the origin of the substance is to be traced to the character of the food, which is more nearly carnivorous with man and the dog and purely herbivorous with the horse, and that its production takes place somewhere in the digestive tract.

COMMUNICATIONS.

STRYCHNIA AS A CURATIVE AGENT IN THE TREATMENT OF ASCITES.*

THOS. J. McKIE, WOODLAWN, S. C.

In our eager and no less industrious search after new and often untried therapeutic agents for the cure of disease, or the relief of human suffering, the older and sometimes more reliable and more useful remedies are in great danger of being overlooked if not entirely discarded from our list of remedial agents.

Having had occasion several years ago to call the attention of the profession to the subject of this paper, I feel that an apology may be due this association for introducing at this time so trite a subject as the treatment of ascites.

Some time ago, while discussing the treatment of abdominal dropsy with a member of this body, he remarked that the treatment was as simple as the cure is easy.

Upon interrogating him as to this all sufficient remedial agent, his reply was mercury, calomel in small and repeated doses. This is truly a simple treatment, though it has not proven to be sufficient, satisfactory or always safe in my hands.

The fact is familiar to all, that dropsy, abdominal or other, has long been regarded as a symptom of disease rather than a disease itself. And, in the language of a most distinguished† writer, it has been affirmed that it would be more philosophical and scientific to treat the original malady upon which the effusion or accumulation depends, to erase dropsy from the list of substantive disease and to place it in the catalogue of mere symptoms.

But this, in my mind, is a very mistaken view of the matter. For, first, it is oftentimes uncertain, while the patient is yet alive, what or where the primary disease may be; and even after death we sometimes can discover no organic change that would satisfactorily account for the effusion. Practically speaking, in such cases the dropsy is the disease, and the sole object of our treatment.

And, secondly, dropsy is in fact to a medical eye in all cases, something more than an effect or symptom of disease. The imprisoned liquid is often a cause of various other symptoms; embarrassing by its pressure, important functions and even extinguishing life. The removal of the dropsy, (although its original cause, of which it was a symptom, may remain behind untouched, to be again productive of effusion under circumstances favorable to its operation) will often restore a person to comparative comfort, or even to what, so far as his sensations and powers and belief are concerned, is to him, for the time, a state of health.

Without essaying any refinement in diagnosis, or attempting to distinguish dropsy as a disease and dropsy as a symptom in the treatment of ascites, it is proposed to speak of it as a disease *per se*, and more particularly of the use of strychnia as a curative agent in that disease. No sound practitioner, however, will close his eyes to any concomitant which may appear, whether it be functional or organic; or fail to supplement any line of treatment with remedies specially adapted to existing conditions whatever may be his faith in that drug or material. Nor would he neglect any febrile movement, where such condition exists any more than he would ignore the existence of an engorged liver, or obstructed portal circulation, or torpid state of bowels, or cardiac or venal derangement. Adjuvants are useful and helpful in all cases.

It is deemed safe and within the limits of conservatism, founded on a somewhat extended experience, to speak of strychnia as a curative agent in the treatment of ascites. While the claim to priority in the use of this agent as above stated is just

*Read by title before the South Carolina State Medical Association, 1894.

†Sir Thomas Watson.

so far as my knowledge goes, it is the result of an accident. Many years ago there came into my hands for treatment a negro woman about forty years of age, and the mother of eight or ten children, who, in the hands of other practitioners in the neighborhood, had gone through the usual course of treatment without avail, and who had already undergone many tappings. In my hands these were continued with considerable regularity at intervals of fourteen, sixteen to twenty days, until paralysis of one side took place. For this strychnia was prescribed, and the trocar or other evacuating instrument was never afterwards neceessary in her case. The dropsy was cured, as was also the paralysis of the leg, though the use of the arm was never fully restored.

Some years after, the case of another woman presented itself. She was a bright mulatto, about thirty-six years of age, the mother of seven children, and had enjoyed good health previous to this attack, which set in with decided inflammatory symptoms rapidly resulting in œdema of the lower extremities soon followed by peritoneal effusion which demanded the use of the trocar.

After a number of tappings the intervals between some of which did not exceed ten days, she began the use of strychnia, and was cured of her dropsy. During the second year afterwards she bore another child, dying five or six years later in the hands of another practitioner, and without any return of her dropsical symptoms.

A still more remarkable case, perhaps, is that of a gentleman forty-eight years of age, who at various times had been in the hands of neighboring practitioners, (as the patient informed me) for treatment of supposed incipient tuberculosis, he having suffered for some time with dyspoena, cough and sanguineous expectoration, followed by wasting, inability to preserve the recumbent posture, œdema of lower extremities, and other evidences of anemia. To be brief, when this patient was first visited, more than a year after the first symptoms presented themselves, he was found laboring under anasarca as well as ascites. There was also distressing dyspnoea inability to rest in the recumbent posture, some cough and tumultuous heart action. In this case the dropsy was evidently symptomatic, and had its origin, no doubt, in valvular insufficiency with blood stasis of the pulmonary tissues resulting in cough with bloody expectoration. Under the use of cardiac sedatives, diuretics and purgatives there was decided amelioration of the more distressing symptoms, but the anasarca, pari pasu with the ascites, advanced until within a few weeks they assumed the most prominent place in the category of symptoms.

With the distressing peritoneal effusion enormously swollen genitals superadded to the general swelling of the body, face and extremities. Soon the cuticle gave way on the lower extremities, discharging each day a considerable quantity of serum.

Under the use of strychnia there was gradual improvement. When last heard from, (three months ago,) this patient was eating and sleeping well, being then about the farm attending to his affairs in comparative comfort, though with some œdema still present in the lower extremities.

A cure was not expected or hoped for in this case, though it seems that impending dissolution has been averted for more than two years under the continued use of strychnia. The use of this was instituted early in this case in connection with remedies previously mentioned, and given in 1-30 gr. doses every eight hours, gradually increasing the dose until the 1-11 gr. was reached, when the muscular pain of the arm became so great as to make it necessary to reduce the dose, or for a time suspend its use entirely. That its physiologic effect shall be experienced seems necessary to its full therapeutic action, and it has been found safe to increase the dose to that extent.

Case 4 was that of a young lady twenty-years of age, who was first seen in April, 1893. She had previously been in charge of another attendant whose service had been, as reported, very irregular, and who had suspected incipient tuberculosis on account of the prominent pectoral symptoms, cough, dyspoena, rather free expectoration, and the known fact that several members of the family had died of that disease.

At this visit, besides great irregularity of pulse beat, there was present dyspoena, slight cough, diastolic heart murmur, œdema of feet and ankles extending nearly to the knees, and ascites so prominent as to offer mechanical obstruction to the respiratory act even in the sitting posture,

recumbency being quite out of the question. This was evidently another case of symptomatic dropsy caused by grave structural lesion of the centre of circulation.

Under the use of diuretics, cardic sedatives, occasional hydragogue cathartics and the constant use of strychnia gradual improvement took place. The patient was so far relieved as to be able to rest in bed, eat well, take out-door exercise, even going so far as horseback riding. At this period treatment was interrupted, and was not renewed, (owing to the absence of the attendant,) until the swelling had again made considerable progress. When treatment was again applied for, and the strychnia given as before, it was without effect, and the patient died eleven months from date of first visit.

This brief and very cursory account of these four cases of ascites in which strychnia was freely used, will, it is hoped, suffice to show the effect, and serve also to bring to the notice of the Association an experience with a remedy, the mention of which, so far as my reading or observation goes, does not appear in our text books, or in current medical literature, as a therapeutic agent in the treatment of ascites.

CASE OF ENDOCARDITIS AND PERICARDITIS WITH EFFUSION—ACCIDENTAL TAPPING OF RIGHT VENTRICLE AFTER APPARENT DEATH—RECOVERY.*

ALLEN THOMSON SLOAN, M.D., EDINBURG, SCOTLAND.

M. B., aged 19 years, a tall, fairly healthy young lady, was seized on 12th May 1894 by a severe attack of erysipelas, which affected chiefly the left side of the face and head, and although it spread over the forehead and part of the right side of the face, was fortunately arrested, under treatment with ichthyol and lanoline externally and iron internally, on the fifth day, and an apparently rapid recovery was about to ensue. The temperature, which at the commencement varied from 103° to 105°, had become normal, all sign of inflammation had disappeared, and a perfect cure seemed established, when suddenly, without any fresh exposure—the patient never having been allowed out of bed—a very severe attack of rheumatic fever developed.

To this there was a marked family predisposition, her father having suffered from a prolonged attack of acute rheumatism, which left him a martyr for sixteen years to subacute attacks, and completely deformed him; and her only brother having twice had attacks of rheumatic fever, and suffered frequently from rheumatic sore throat. Her mother and two sisters are alive and well; but her father, who at the time of her attack was suffering from tuberculosis of both lungs —the result of influenza—has since died. Her maternal grandfather and grandmother are octogenarians and in good health, but on the paternal side there is a distinct tendency to phthisis.

Her previous illnesses all indicate the same susceptibility to rheumatism. When two months old she suffered from bronchitis, which lasted about a fortnight. At five years of age she had rheumatic fever, and two years afterwards suffered from measles, which was followed by a second slight attack of rheumatic fever. Between the ages of nine and ten she had diphtheria, but for the next eight years enjoyed perfect health. In the beginning of February, 1893 she was attacked with scarlet fever so severely, that from the outset she was put on a water-bed, and in spite of daily 30 gr doses of salol and continued lying between blankets, she was seized with a third sharp attack of rheumatic fever, with accompanying endocarditis. This left a well-marked systolic mitral murmur, which, however, in the course of a few months entirely disappeared, and with the exception of slight œdema of the right foot, she enjoyed robust health till within a few weeks of her

*Read Before the Medical-Chirurgical Society of Edinburg, December 5, 1894.

present attack, when she began to feel her duties as a school teacher rather fatiguing, and doubtless the anxiety regarding her father's health predisposed her to the attack of erysipelas, which was the starting-point of the present, her fourth and most severe attack of rheumatic fever.

Salicylate of soda, in 10 and then in 15-grain doses every three hours, along with aromatic spirits of ammonia, was substituted for the quinine and antipyrin, which had been given along with the iron during the attack of erysipelas, and had been very badly borne. From the 17th to the 22nd fair progress was made, the temperature varying from 99° to 103°, but with a distinct tendency to an evening rise. No great relief, however, was got from the pains, which were general throughout all the joints, and were most severe in the muscles of the calves. An 8-grain Dover powder was given at bedtime with marked benefit, as a few hours' sleep was induced, and the restlessness, which had been characteristic from the first, somewhat allayed. A daily careful examination of the heart revealed nothing till the morning of the 24th, when slight præcordial pain and a feeling of oppression about the chest was complained of, followed in the evening by well-marked friction, the "to-and-fro" murmur being audible over the whole base, but loudest and apparently nearest to the ear over the pulmonary area. The dose of salicylate of soda was increased to 20 grains every four hours, and digitalis added to quieten and strengthen the pulse, which from the beginning of the attack had varied from 100 to 116 per minute, but had been of fair strength, regularity, and volume. Warm poultices and sinapisms were applied locally, with the result that in five days the friction had entirely disappeared, and the patient again seemed in the fair way of recovery. Still the temperature kept irregularly rising and falling in a suspicious manner without sufficient ascertainable cause, and the muscular pains in the limbs became even worse. Salicin alone, and combined with antipyrin, was tried, but ineffectually; and considering the attack to have a possible septic origin, salol in 12-grain doses every four hours was substituted, with a slight resulting decrease in fever, but no diminution in pain. In fact, the only drug administered with certain benefit was the old-fashioned but reliable Dover's powder. During all this time the services of a skilled nurse had been utilized, and every precaution as to diet and the general treatment of a patient suffering from acute rheumatism had been most scrupulously and carefully observed. The urine, tested twice a week, presented no abnormality other than scantiness in amount and excess of urates.

From the 28th of May to the 4th of June the condition of the patient remained much the same, but on the evening of this day there was a return of the friction, and in addition a well-marked systolic mitral murmur was audible. Hourly, almost, a change for the worse progressed, hastened by the thought of parting from a dying father, who was being removed to the country in the vain hope of prolonging his life, and without an interview. Every movement was accompanied by excruciating pain, mostly in the muscles of the lower limbs; nourishment was taken, with difficulty, owing to occasional attacks of sickness; an irritable, hacking cough developed; the pulse became rapid—120 to 140 per minute—feeble, and dicrotic, and the respirations were greatly increased reaching to 30 and 50 per minute. The livid, anxious countenance, the pallor of the lips, the working of the alæ nasi, the dilatation of the veins of the neck and the increased general restlessness, all indicated rapid effusion into the pericardium, which physical examination too truly revealed. The area of cardiac dulness was greatly increased, extending fully half an inch to the right of the sternum, up to the second interspace above, but below and to the left was indistinguishable from a dulness which extended over the whole of the left lung, doubtless due to compression from the bulging pericardium, and probably also to some actual pleuritic effusion, as all breath-sounds were inaudible over the whole of the left base, and up to the middle of the scapula. Friction was still to be heard, but the actual heart sounds were distant, feeble, and obscured.

From the 8th to the 11th matters got worse, the changing color of the face indicating the possibility of a fatal faint at any moment, and an ever-present terror of approaching death adding greatly to the patient's discomfort and pain. By this time all anti-rheumatic remedies had been stopped, and stimulants, in the form

of champagne and brandy, freely given, while a mixture of strophanthus, strychnine, and iron was added with a view to keep up the heart's action. Two blisters were applied over the præcordium, and sinapisms to the bases of the lungs. Curiously, all the time the patient could only lie in an absolutely recumbent position, any attempt to raise her with a view to ease the breathing having quite the opposite effect.

My mind was gradually being made up that tapping the pericardium alone would benefit the patient, so on Tuesday, June 12th, Dr. Bramwell was called in consultation. So grave was the patient's condition during the afternoon that the subject of tapping was not even mentioned between us, and the application of another blister was the only remedy suggested. In addition to all the other symptoms, considerable difficulty in swallowing had arisen, showing further increase in the effusion. The blister was applied a little lower down and more to the left than the previous ones, exactly over the apex-beat, which now corresponded to the left nipple.

On the following morning, June 13th, I set up the aspirator and had it ready exhausted in an adjoining room, though the friends of the patient greatly objected to its being used. The pulse, which had been so rapid, had become alarmingly slow—80 per minute—and the nurse was warned if there was further slowing to send at once for assistance.

During the afternoon the patient was seen by Dr. Calder of Leith—a personal friend—who was then of opinion that, tapping or otherwise, she had only an hour or two to live.

About 8 P. M., on my way to the house, and whilst about four minutes' walk from it, I was met by a young lady, who told me to hurry, as my patient was just dead. I ran as quickly as possible, and found that Dr. James Smith had been summoned, to find her either in a fit or faint. The pulse was uncountable and hardly to be felt, and the livid pallor of the face, profuse, cold perspiration, and changing, startled expression, indicating approaching death. First, 30 minims of ether were injected into the arm, and then a sudden dilatation of the pupils and rapid receding of the pulse warned us of further need of stimulation, and 30 minims were injected into the left breast. I proposed tapping; but as the friends were anxious first to see Dr. Bramwell, Dr. Smith ran to telephone for him. Immediately afterwards the heart and respiration stopped, and in the moment of excitement I jumped up, seized the aspirator, and plunged the needle into the fourth interspace, about half an inch to the left of the sternum and a little below the left nipple. To my astonishment, from 8 to 10 ounces of pure blood flowed rapidly into the bottle of the aspirator and then suddenly stopped, and to my dismay I found I had penetrated a cavity of the heart. As I was slowly withdrawing the canula, regretfully telling the nurse it was all over and to close the patient's eyes, to my surprise the heart made first a feeble, irregular movement, then gave a sudden strenuous jump and, finally, like a pendulum regaining its swing or a runner his stride, it started to beat again in the race for life. In moments of intensity it is difficult to estimate time, but I should say fully half a minute had elapsed between the introduction of the needle and the restarting of the heart-beats. It was an extraordinary sensation to feel the heart beating more and more forcibly against the point of the canula, which was gradually withdrawn so as not to further injure the heart-wall.

I was standing with my thumb on the puncture made by the needle, when Drs. Bramwell and Smith made their appearance. My uppermost feeling at first, was one of regret that I had converted a patient practically dead into one apparently dying, and sincerely did I lament she had not been left to pass away in peace, for a most pitiful scene was now enacted for an hour. Occasionally there was given a heart-rending shriek, quantities of frothy mucus were half-coughed, half-vomited and had to be swept out of the mouth with a towel, the blood went ebbing and flowing from the cheeks, which were first ashy-grey then purplish in hue, the pupils were dilated to their fullest extent, the running, following pulse was quite uncountable and the patient had every appearance of one dying asphyxiated. Another dram of ether was injected, with the result that the patient became maniacal, and Dr. Bramwell's suggestion, first one-sixth and then another one-sixth of a grain of morphia was administered hypodermically to keep her quiet. This had a slightly soothing effect, and Drs. Bramwell and

Smith now left, thinking it quite impossible the patient could live through the night. In another hour, however, her aspect had vastly improved, the lividity of the countenance and pallor of the lips had disappeared, the breathing was easier and the mania was succeeded by the most delightful feeling of intoxication, the patient repeatedly breaking out into ripples of laughter, and saying, "Oh, how nice! What a dear, kind doctor!" "Oh, how funny! Needles and pins, needles and pins running down both legs and arms!" In another half hour she was able to recognize her mother, who had been brought in from the country. The services of two fresh skilled nurses were obtained, and with injunctions that she should be freely stimulated with champagne and brandy, she was left for the night. The blood, which filled one-third of a 30 oz. Winchester jar, had formed a solid clot, and had to be broken up with a stick and dissolved with soda and hot water before the bottle could be cleaned. In it there was no apparent mixture with serum, and clotting had taken place early and was specially firm. The smallest size of the ordinary aspirating needle was used.

During the night the patient was inclined to wander, and the pulse remained very rapid, changeable and irregular, while the respirations varied from 22 to 34 per minute, broken at intervals by a prolonged sigh. Occasionally great anxiety was caused by the deathly pallor of the lips spreading round the angles of the mouth, at which times a little brandy or champagne was administered in teaspoonfuls. In the morning consciousness completely returned, and the patient was able to take half a cup of tea and a biscuit. She had no recollection whatever of the dreadful crisis she had passed through, having been quite unconscious during the operation of tapping; and when puzzled as to the piece of plaster over her left breast, was told it was part of the dressing of her blister, as it was thought wiser to avoid any excitement. The pulse varied from 118 to 122 per minute, and was still very feeble and irregular, with a long pause at every fourth beat. The most absolute rest was enjoined; liquid nourishment was given in small quantities frequently, and stimulant only in drachm doses, and with caution, in fear of over-exciting the already too tremulous heart's action. In the afternoon the temperature rose to 101°-4, but this was accounted for by the exhaustion and the general feeling of soreness, due to continued lying in the same position. As there was still a tendency to mental excitement and no further sleep had been obtained, at 12.30 A. M., 15 grs. of bromide of potassium were given, after which she slept till 2 A. M. At 4.30 there was great restlessness, and other 15 grs. were given, with the result that repeated short sleeps were obtained between the times of administration of nourishment. Two days after the operation the temperature fell suddenly to normal, and the pulse from 104 to 40, which occasioned great anxiety; and this happened from time to time, till the pericardial effusion cleared away about eight days afterwards, while the slightest movement on the part of the patient caused immediate paling of the lips and face.

It is needless for me to detail the daily progress of the case, which was hourly observed and noted by the two nurses to whose superb after-attention the patient owes her life. It will suffice for me to point out that after the fifth day there was no rise in the temperature above 99° until July 2d, and it was due to slight gastric disturbance, the consequence of overfeeding; that the pulse first became regular, then gradually slower, till on the 22d of June it reached the normal rate of 76, and the respirations, which had varied from 22 to 30, correspondingly declined to 18 per minute. During the first twenty-four hours no urine was passed, and for seven days after only 12 to 14 ounces daily, thick with urates; but the patient continued at times to perspire so freely that her flannel gowns had to be changed frequently. The first urine passed contained no sugar nor albumen, but was greatly discolored owing to the previous free administration of salol. Solid food in the form of white fish was first given six days after the tapping, and the cardiac tonic of arsenic, strophanthus, strychnine and iron resumed. Fruit in the form of bananas and oranges was allowed, and strong soups flavored with vegetable juices given with a view to combating the profound anæmia which had ensued. Stimulants were only given when specially called for, and the bowels relieved by glycerine enemata. The only

complaint the patient had was about the soreness of her bones, owing to her great emaciation; but an attempt to put her on a water-bed caused such alarming faintness it had to be abandoned.

It is the most extraordinary fact that here was a case of rheumatic fever, apparently of septic origin; which no therapeutic agent with the exception of the opiate, had done anything to alleviate, which almost nightly for three weeks had produced a temperature of 104°; and which, with its complications of endocarditis and pericarditis, had nearly caused the death of the patient, suddenly and finally arrested by the heroic process of drawing off ten ounces of blood direct from the heart. At no time afterwards did the patient suffer from the very slightest rheumatic pain, whilst previously she was practically never free from such night nor day.

For the first five days physical observation could only consist of stethoscopic examination over the heart; but till Tuesday, the 20th June, the heart sounds were represented by irregular, muffled thumps, and were quite indistinguishable in any area. On that day they could be faintly heard and localized—the first sound feeble in the aortic, tricuspid, and pulmonary areas, the second relatively much accentuated; while in the mitral area, and especially over the left nipple, a soft blowing systolic murmur was distinctly audible, with a less certain pre-systolic. Daily the sounds became clearer, and when the patient became stronger, percussion revealed the gradual disappearance of the pericardial effusion, which was further hastened by the daily external application of iodine. A fortnight elapsed before the lungs could be satisfactorily examined, but at the left base there was still extensive dullness and absence of breath-sounds. Rubbing with turpentine, iodine and blister were successful in removing this, and in three weeks, except for great debility, the patient was physically perfectly well, the systolic mitral murmur being the only persistent indication of what she had passed through.

Dr. Bramwell, who daily had looked for some announcement of the patient's death, kindly revisited her on Friday, the 23d, nine days after the tapping and found the young lady whom he had left *in extremis*, apparently without the faintest hope of recovery, enjoying, through the kindness of a too indulgent nurse, a plate of strawberries and cream. In a month the patient was allowed up on a couch, and in another week to make personal efforts which had previously been forbidden; and it was the utmost gratification to me that within seven weeks from the time of cardiac aspiration she was able to be driven seven miles into the country to visit her father, the shock of whose death a day or two afterwards she stood remarkably well. A week after this she was sent to the country and since then has enjoyed perfect health.

December 5th, 1894.—The patient continues in excellent health; she has had no return of the rheumatism, and the cardiac murmur has entirely disappeared.

Sheridan's Wit.

Richard Brinsley Sheridan was never at a loss to exhibit his wit. Once while visiting, feeling rather weary and wishing to rest, he was asked by a fellow-guest whom he did not admire if he did not wish to accompany her for a walk.

Glancing out of the window, Sheridan replied: "It is very cloudy. We shall be caught in the rain."

The other waited awhile. Shortly the sun came through the clouds. "Shall we go now?" she asked. "It has cleared up."

"Why, yes; so I see," said Sheridan. "It has cleared up enough for one, but not enough for two. You go,—*Harper's Young People.*

A Treatment for Acne of the Face.

In an abstract from the *Bulletin General de Therapeutique* which appears in *Lyon Medical*, the writer gives the following formula which, he says, has often been employed at Saint Louis with success: Fresh lard, 750 grains; sublimed sulphur, 105 grains; beta-naphthol and styrax ointment, each, 30 grains. Applications of this mixture should be made with strong friction every night for a week, then interrupted for six days when they may be repeated if necessary, although it is often useless to do so. If there is an appearance of small acute clusters, which generally show themselves toward the second day, the acne is ordinarily cured or very much ameliorated at the end of a week.

TRANSLATIONS.

THE CONGENITAL AND HEREDI TARY ORIGIN OF CANCER.

Critzman (*Le Bul. Méd.* November 7, 1894) declares cancer to be a tumor developed at the expense of a preëxisting epithelium of which the histologic varieties engender tumoral varieties. The fundamental element of cancer is the epithelial cellule, and the malignity alone does not suffice to characterize this neoplasm. There may be eliminated, therefore, from the class of cancerous productions every neoplasm the primordial constituent element of which is drawn from the mesoderm (tumors of the connective tissue group.) Thus simplified, cancer still presents a certain complexity from the point of view of the causes invoked to explain its appearance and its evolution.

Why does cancer develop? What is its nature? Why does it generalize itself? The answers to these different questions are not wanting. The ancients, struck by the coincidence of cancer and the great emotions, chagrin especially, have attributed to the latter the responsibility of the neoplasmic production, and, in modern times, the death of Napoleon succumbing after terrible grief to a cancer of the stomach is an impressive example. This must, however, be only an occassional cause. The infectious nature of cancer, its generalization, its inoculability have induced many savants to search in parasitic life the clue to cancerous productions. The germ has not as yet, however, been discovered. The cancerous graft has been clearly placed in evidence by Virchow. The epithelial cellule characteristic of cancer is equally its cause; effecting its division other than in sound tissue the cancerous cellule is a teratologic epithelial cellule, the proliferation of which will give birth to a monstrous epithelial tissue able to engraft itself by apposition and by generalization. Invading the lymphatic ganglions the cancerous cellule multiplies, and also gives rise to cancerous metastases which are in structure always identical to the tumor to which they owe their existence.

What is the origin of this epithelial cellule of which the development, always tardy, gives origin to cancer?

Cohnheim attributes to tumors in general a congenital origin. For teratomata, and especially dermoid cysts, this hypothesis has received its demonstration; for other tumors, and cancer in particular, the cause is explained most simply in the following manner: At an initial stage of the embryonic development there is produced in one of the portions of the fetal economy, more cells than are necessary for the construction of the part in question. These cells heap up in excess to a given moment, able to develop with all of the intensity of their embryonal nature under the influence of a banal cause which manifests itself, whatever may be its nature and its form, as a circulatory phenomenon—a hyperemia or an anemia. The experiments of Leopold seem to give reason of this conception. Fragments of fetal tissue taken during its intra-uterine life and introduced into the organism of a similar adult animal, continue not only to live but multiply in a manner truly surprising.

The congenital nature of cancer explains sufficiently the heredity of this tumor. Statistics of great value bear very conclusively upon this point. Cancerous patients are able to transmit by heredity cancer to their child. Butlin, who has attempted to construct the family history of cancer of the heart, has concluded that heredity is encountered in the proportion of 1 to 3.

A New Treatment of Whooping-cough.

Lyon Médical publishes an abstract of an article from the *Médecine Moderne* in which M. de Chateaubourg describes a new treatment of whooping-cough, which consists in injecting, subcutaneously, two cubic centimetres and a half of a ten-per-cent. solution of guaiacol and eucalyptol in sterilized oil. After the third injection the fits of coughing diminish noticeably, the appetite returns, and, as the vomiting rapidly ceases and the general conditions begins to feel the good effects of the treatment, the whooping-cough disappears at the same time. The author reported five cases.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

CHLORATE OF POTASH AS A TOOTH POWDER.

Dr. Unna (*Deutsche Medizinal-Zeitung*, No. 103, 1894) recommends powdered chlorate of potash as the best tooth powder as well as for general disinfection of the mouth. The moist brush is dipped into the powder and as much used as it will take up. The profusely secreted mucus and saliva form a paste with which the teeth are easily cleaned; this is followed by a thorough rinsing of the mouth to remove the drug. The use of this tooth powder is followed for a long time, by a very clean and somewhat salty taste in the mouth, for it cleanses by producing a flow of the natural buccal secretions and its action is not confined to the mouth alone, but to the tonsils and fauces and to any portion of mucous membrane with which it may come into contact. He knows no better remedy which will remove fetidity of the breath, due to putrifaction of food and the secretions of the mouth. He has seen a great number of cases where patients have consulted physicians on account of a bad breath which led them to suspect either a disease of the nose, throat or lungs and which promptly disappeared after use of this simple measure. In cases of fissures or ulcerations in the mouth where the clear drug would cause a great deal of pain he employs a paste containing a smaller percentage and made after the following formula:

Calcium carbonate	āā
Rhizoma iridis	
Soap	
Glycerine	

Equal parts of this base and the chlorate are mixed; it is best dispensed in collapsible tubes. He knows of no better remedy for daily use, nor in the cleansing of the mouth and teeth in all infectious diseases and especially in stomatitis of mercurial origin.

RAPID STERILIZATION OF WATER.

Dr. Grimbert (*Apotheker-Zeitung*, No. 46, 1894) says that one may rapidly sterilize water and at the same time retain its gases and salts by placing it in a thick glass bottle with a patent closing apparatus such as a beer or soda-water bottle and then placing it into a water-bath and keeping it there for one-half hour, at a temperature of 100° C. Water thus sterilized remains clear, of an agreeable taste and retains its salts in solution.

SILK SUTURE SILK IN ANTISEPTIC SOLUTIONS.

Dr. Van Ketel (*Pharmaceutische Zeitung*, No. 68, 1894) has attempted to discover why the solutions of the bichloride in which suture silk is kept in so liable to develop flakes due to various microörganisms. He has found, from experiment, that the silk extracts the antiseptic from the solution; even in the course of twenty-four hours it will withdraw the bichloride from a ½ per cent. solution so that algæ will grow luxuriantly in it. He thinks it probable that the albuminoids and similar substances in the silk enter into combinations with the sublimate. Therefore, he would recommend keeping the silk in absolute alcohol and only placing it into a ½ per cent. sublimate or a 1 per cent. sodium chloride solution immediately before using.

ERUPTION FROM SALICYLATE OF SODA.

Dr. Raff (*Muenchener Medicinische Wochenschrift*, No. 26, 1894), recently observed after administration of twelve grams (℥iij), of the salicylate of soda to a woman of sixty years for an attack of rheumatism, the following condition, which set in after the first teaspoonful: face pale and swollen, great weakness and confined to her bed; both knee-joints greatly swollen and painful. The face presented reddish spots and vesicles behind the ears and the lips were covered with bloody crusts. The hands, arms and nates were covered with a pemphigoid eruption of vesicles and bleeding and oozing patches. Treatment consisted of application of borated vaseline and later, a continuous bath during the day. On the fourteenth day of the disease as a right sided pleuritis had developed and the articular affection remained unchanged the remedy was given again, in a dose of

* In charge of the translator, F. H. Pritchard, M.D.

one gram; in an hour and a half the patient had a chill and the next day a diffuse scarlet redness was seen to cover the whole body. The whole skin appeared, in toto, swollen, while the temperature was elevated. The following morning it had entirely disappeared. Eruptions have frequently been observed after salicylic acid either as erythema, urticaria, vesicular dermatitis, purpura or gangrene. Dr. E. Beier, of Berne, Switzerland (Archiv F. *Dermatologie und Syphilis* Bd. XXVIII, Hft. I) recently observed a similar case where after six grams (ʒjss) of the salicylate of soda an erythematous and pemphigoid eruption of the whole body appeared and, though the remedy was immediately discontinued it persisted and exacerbated after repeating the remedy, but with continued administration, decreased in severity. The local application either in plaster or solution also gave rise to local eruptions of vesicles. The case is of interest on account of the persistence of the symptoms long after discontinuing the drug.

BRANDY SUBCUTANEOUSLY IN CHLOROFORM ANESTHESIA.

Dr. Poucel (*Gazette des Hôpitaux,* No. 99, 1894) for the past four years has employed hypodermics of brandy in chloroform anesthesia and in five hundred cases has always avoided disagreeable complications. He follows, in administering the anesthetic, the drop-by-drop method and when the patient's face becomes pale and the pulse also becomes small and weaker, he injects brandy. The stimulant is diluted with two parts of water and kept ready in a hot water bath at about the body temperature. The outer side of the thigh is usually chosen as the point of injection and about a syringeful introduced into the circulation. The injection may be repeated if the condition of the heart requires it. In a laparatomy, on an average, ten syringefuls were used though as high as a hundred have been given. In cachectic subjects they are made before, during and after the operation. The results were most striking in those with heart diseases, alcoholists, consumptives, little children and old persons.

COCAINE IN DRAWING TEETH.

Dr. W. Lepkowski (*Central Blatt Fuer Chirurgie,* No. 51, 1894) uses cocaine very extensively in dental work and is well satisfied with the results. A three per cent. watery solution is injected around the tooth, into the gum, until it turns entirely white, when further injection is quite painless. One should begin on the lingual side and as a rule, 0.007–0.015 will suffice for complete anesthesia. In extracting the last upper molar he warns against injecting into the fold of mucous membrane back of it as it is quite prone to be followed by symptoms of poisoning. As the first injection is a painful one he also applies to the gum a 10 per cent. solution and injects a 1 per cent. solution around the tooth. Injections into abscesses produce violent pain though one may safely inject into inflamed and infiltrated gums. He does not wait a few minutes after injecting but extracts at once. He has found by experiment that 1 per cent. and 3 per cent. solutions of cocaine arrest the development of cultures of pyogenic microörganisms.

IPECAC NOT AN OXYTOCIC.

Dr. A. Keilmann (*Petersburger Medicinische Wochenschrift,* No. 24, 1894) has tried the tincture of ipecac as an oxytocic in weak uterine contractions as recently recommended by Drapes and Utt of St. Petersburgh and denies that it has any such powers. He would rather advise pushing the head from above down into the pelvis, but under anesthesia.

PETROLEUM IN PULMONARY TUBERCULOSIS.

Dr. Pellisier (*Bulletin Général de Therapeutique,* Tome CXXVI, p. 416) observing that workmen about oil wells are rarely affected with consumption, tried the filtrated crude oil, in treating this disease. It was given in capsules and inhalations of its vapor used at the same time. The results, he claims, were astonishing; the cough and sweats disappeared, the appetite and sleep became normal and the affected portions of the lung healed. Attempts to give it in clysters failed from its slight absorption.

SULPHUR IN DIPHTHERIA.

Dr. C. G. H. Baemuler (*Centralblatt Fuer Die Medicinischen Wissenschaften,* No. 47, 1894) speaks well of the local ap-

plication of sulphur in diphtheria. It is insufflated three to four times a day, in a goodly quantity, upon the affected mucous membrane. If the disease extend deep down into the trachea it is, of course, inapplicable. Its action seems to be purely local and therefore is only indicated in the early stages of the disease before general symptoms have set in.

THUJA OCCIDENTALS AS AN ABORTIFACIENT.

Dr. Kalt (*Schweizer Correspondez-Blatt*, No. 8, 1894) reports the case of an unmarried girl of eighteen years, who seven months pregnant, drank a decoction of thuja occidentalis (arbor vitæ or tree of life). This was followed by a violent nephritis, cystitis, eclampsia and bronchial catarrh. Fourteen days after an abortion followed, the child living twenty-six hours. The placenta showed several infarcts. Eleven days after her labor thrombosis in both saphenous veins was noticed. She recovered only very slowly.

LEUCOPLASIA BUCCALIS AND EPITHELIOMA

Dr. Le Dentu (*Journal des Mâladies Cutanees et Syphilitiques*, No. 11, 1894) states that leucoplasic patches in the mouth very frequently degenerate into epitheliomata. Without being a preceding stage of this form of cancer, yet there is a decided disposition to it on account of their predisposition to degenerate. Therefore as soon as one observes a leucoplasic patch to undergo papillomatous transformation or to present a fissure or ulceration, one should treat it surgically.

Dr. Rosenberg (*Ibidem*) speaks very highly of the iodide of potash in the treatment of leucoplasia buccalis. He advises a concentrated solution as follows:

Distilled water.....	100	o	℥ iij, ℥ j
Iodide potash	10	o	℥ ijss

Apply locally by means of a camel's hair brush.

Treated thus he has seen a leucoplasia disappear which had lasted for seven years, and which had resisted the most varied treatment.

Dr. Leistikow (*Ibidem*) advises the following paste in the same disease:

Finely powdered silex.....	3	o	grs. xlv
Resorcine	6	o	℥ jss
Lard.....	1	o	grs. xv

Apply this paste to the patches between meals and on going to bed upon small tampons, fixed in the mouth and rub the patches also with it well. At the end of eight to fourteen days they will shrivel up, fall off and leave a red and congested mucous membrane. This is then treated with the balsam of Peru. Healing will take place little by little. The silex renders the penetration of the resorcine easier and acts as a mechanical adjuvant.

HYPODERMIC INJECTION OF SALT WATER IN PERNICIOUS ANEMIA.

Dr. K. E. Lindén (*Finska Laekaresaellskapets Handlingar*, bd. 36, s 35, 1894) records a case of pernicious anemia where he employed subcutaneous injections of salt water with excellent results. Two injections in all were given, each containing 825 gms. of the following solution:

Cooking salt.....	4	o	℥ j
Bicarb. soda.....	3	o	grs. xlv
Distilled water.....	1000	o	℥ xxx j ℥ ij

An improvement set in immediately after the first injection; the sensation of obscuration of sight disappeared, the somnolence decreased, and the appetite increased. Immediately after the second one the pulse became stronger and fuller, as well as slower, the abnormal sensations of taste and smell vanished, and on the third day, after this second one, the appetite was decidedly ameliorated and the general condition greatly for the better. Three weeks after he was able to be about.

ANTISEPTIC EYE SALVES.

Dr. Bach (*Lo Sperimentale*, No. 35, 1894) has experimented with a number of antiseptic eye-salves especially those with vaseline as a base, and he finds them of undoubted value on account of their decided antiseptic action. Those of iodoform, boric acid and yellow precipitate are however, without antiseptic properties. On the contrary, one of the bichloride, 1:3000 or the nitrate of silver, 2 per cent. will destroy the germs in a short time. These properties are not affected by mixing with other liquids as a solution of common salt or tears which is of great practical importance. Vaseline he has found to be a very poor soil for germs for it will remain sterile for a long time, and does not become rancid. Therefore, he advises heartly eye salves in preference to collyria, particularly, where the patient is to apply them at home.

BACTERIOLOGICAL NOTES.

THE BACILLUS OF THE PLAGUE IN CHINA.

The discovery of Kitosato of the specific cause of the plague which has caused such frightful epidemics in China, has already been announced. It was found that this terrible disease was one of the "filth diseases," and caused by a micro-organism which belongs to the septic bacteria. Yersin (*Ann. Inst. Pasteur*, VIII, 1891, p. 662) gives the results of further investigation of this organism. He found that the enlarged lymphatic glands in this disease contain large numbers of a short, stumpy bacillus with rounded ends. It stains readily with ordinary aniline dyes but does retain the coloring matter when treated after the Graus method. Frequently a polar stain is observed. Not infrequently a capsule is observed. It is easily cultivated on agar, glycerine-agar, blood serum, and in bouillon. The best medium was found to be composed of two per cent. alkaline peptone and one to two per cent. gelatine. In these cultures this organism appears on microscopic examination, as short chains of bacilli, with bulgings in some places. Involution forms are frequent, especially in old cultures.

The pathogenesis of this organism is quite marked. Rats, mice and guinea-pigs when inoculated with the bubo-pulp invariably die with lesions characteristic of the disease and containing the bacilli in large numbers in the glands. The first tubes inoculated develop very slowly, but subsequently the cultures grow more rapidly but the virulence of the bacteria is diminished. By continued subcultivation they become innocuous for experimental animals. Feeding experiments showed that the disease could be produced by feeding as well as by inoculation. The specific bacillus of this disease has been found in flies and in the surface soil to a depth of from 4 to 5 cm.

IMMUNITY AS ILLUSTRATED BY EXPERIMENTS WITH CHOLERA.

Metschnikoff (*Ann. de l'Inst. Pasteur*, 1894, pp. 529-89) discusses the subject of cholera and vibrios in relation to immunity and intestinal cholera. The conclusions reached are of considerable interest and are appended without further reference to the details of his investigations:

1. "Local immunity cannot be explained by particular conditions which prevent the microbe from living, for it may be found beyond the cholera area and in places quite free from it.

2. "Local immunity cannot be regarded as an unconscious and permanent vaccination of the inhabitants.

3. "The blood of persons residing in exempt places does not protect against Koch's vibrio.

4. "The injection of cholera cultures does not protect.

5. "The development of the cholera vibrio is considerably affected when growing in association with other microbes.

6. "The immunity of animals to intestinal cholera is in a great measure due to the inhibitory influence of the flora of the gastro-intestinal canal on the cholera vibrio.

7. "As long as young rabbits are being suckled they are very sensitive to the cholera vibrio, and this cholera is aided by the action of certain microbes.

8. "Young guinea-pigs are less sensitive than young rabbits to intestinal cholera.

9. "Young rabbits cannot be vaccinated successfully against intestinal cholera either with sterilized or living cultures.

10. "Young rabbits may be occasionally vaccinated successfully by means of the serum of animals vaccinated against cholera peritonitis. Normal horse serum is useless.

11. "The attempts to prevent cholera by means of microbes have shown that bacteria exist in the alimentary canal in-

hibitory of the cholera vibrio, but at present the results are inconclusive.

12. "In the immunity and receptivity of man and animals to intestinal cholera, the microbic flora of the alimentary canal plays an important part. Relying on this fact we may readily reconcile the fundamental truth that the vibrio of Koch is the specific cause of cholera with the data of epidemiology, especially with the influence of places and time on the progress of cholera epidemics."

INVESTIGATION OF COW-POX.

At the meeting of the Association of American Physicians, in Washington, D. C., 1894, Dr. H. C. Ernst of Harvard Medical College, read a paper on the bacteriological investigation of cow-pox. The material was largely from the work of Dr. Martin (deceased). A large number of cultures were made from the pustules and bacteria isolated with which the disease was produced in calves but rarely in children. The outcome of these investigations is briefly stated in the results formulated by Ernst (*Transactions Association Am. Physicians*, 1894):

1. "The germ of cow-pox is a bacterium.

2. "This bacterium is, in different stages of development, in the form of a coccus or of a bacillus.

3. "It can be isolated and grown in pure culture on blood-serum at the temperature of the blood.

4. "Inoculation on the calf from such cultures readily produces the typical cow-pox, while inoculations in man have, so far, produced typical cow-pox but once in eleven times."

Dr. Ernst continues that, all that remains to be done now is to find under what conditions to grow pure cultures that may be uniformly relied upon for vaccination in man.

PROTOZOA IN VARIOLA.

Siegel (*Deutsch Med. Woch.*, 1893, No. 2, p. 29) injected vaccine lymph into the peritoneal cavity of a calf and produced nodular excrescences on the omentum of this animal, which on cultivation yielded cocci. These micrococci when injected into the skin of calves produced pustules, but they were in no way comparable to the vaccine process. Löeffler, in 1890, described protozoa and zoospores in the substance of, and between the epithelial cells from pock. These bodies have been looked upon by certain pathologists as nuclei and parts of nuclei, or more or less altered fragments of the epithelial cells.

OUT-OF-THE-WAY MEDICAL PRACTICE.

Those whose duties lie in towns where locomotion is easy, and where even night visits can be made in comparative comfort, can hardly realize the difficulties of medical practice in sequestered spots, and among sparsely populated islands. An apt illustration came under our notice last week, which will doubtless interest our readers to recapitulate. During a gale on Sunday night, a fire an the south end of Ailsa Craig, a bare and desolate rock in the middle of the Firth of Clyde, and the return of a homer pigeon, intimated that a doctor was wanted on the rock. As the weather was stormy and a heavy sea running right in the face of the Craig, it was deemed necessary to send off the life-boat, as an ordinary fishing boat could not have effected a landing. Consequently, Dr. Alex. McDougall, of Girvan, Aryshire, was taken out in the life-boat at 11 P.M. With some difficulty he was landed and found that one of the lighthouse keeper had been blown down by the gale and that three of his ribs were broken. The life-boat returned with the doctor at 10 A.M. next day after a dangerous trip of eleven hours; a professional visit rather out of the common run, and not far removed from heroism.—*Med. Press.*

CORRESPONDENCE.

ADVISABILITY OF VACCINATION DURING THE EXISTENCE OF A SKIN ERUPTION.

EDITOR MEDICAL AND SURGICAL REPORTER:

DEAR SIR:—The question as to the advisability of vaccinating a person during the course of an eruption of the skin having been frequently in evidence, I take the opportunity at the present time to make answer through the medium of your journal. Within the past few months the question certainly has arisen more than at any other time owing to the apparent fear that we would be visited by an outbreak of variola. It is certain that the patients themselves often fear vaccination during the existence of the skin condition, because of the danger of making their feelings much worse than they have been with the cutaneous manifestation. While this is to a certain extent well founded, I do not think any one will be afraid when they are aware that no danger to life will intervene. Within the passed few days the question has been asked by the parent of a child having psoriasis, he stating that wherever the child was bruised he would be confronted with a new psoriasis lesion in a few days. Naturally one would hesitate before giving a positive opinion in such a case, on account of the supposed idea that psoriasis often occurs after wounds of any character. Having been asked an opinion in this case I did not hesitate to give the following advice, that I thought it would not be inadvisable to vaccinate. And I cannot hesitate to give the same opinion in cases of any eruption of the skin. I would advise that vaccination be performed in any case of an eruption of the skin. J. ABBOTT CANTRELL, M.D.

MORPHINISM IN CHILDREN.

EDITOR MEDICAL AND SURGICAL REPORTER:

SIR:—I am desirous of adding to the clinical literature of morphinism in children, and if any reader of your journal has noted a case and will send me details, I'll appreciate the favor and give full credit.

J. B. MATTISON,

Brooklyn, N. Y.

THE INFLUENCE OF ALUM, ETC., ON DIGESTION.

It is generally believed that aluminum compounds, which have been used extensively in the adulteration of flour and in baking powders, both impede digestion and have an injurious effect on the digestive organs. In a recent series of experiments by Bigelow and Hamilton (*Jour. of the Amer. Chem. Soc.*) the influence of these compounds was studied, not only upon the digestive action of pepsin and hydrochloric acid, but also upon artificial digestion in pancreatic juice. Alum interfered materially with the action of the gastric juice, but the pancreatic juice effected the digestion of the remaining portion of food, which should have been digested by the pepsin. The same was true of the digestion of matters containing aluminum hydroxide. The action of aluminum phosphate was quite different, however, for notwithstanding the supposed insolubility of this compound, ten or twelve per cent. of the albuminoids which were digestible in the presence of alum or aluminum hydroxide appeared to be insoluble in the presence of an equivalent amount of the phosphate.—Ernest Ellsworth Smith, Ph.D.

EDITORIAL.

TENEMENT HOUSES AND PUBLIC HEALTH.

The New York Legislature of 1894 enacted a law authorizing the Governor to appoint seven citizens and residents of New York, as a committee, to be known as the Tenement House Committee, to make careful examination into the tenement houses of the city of New York; their conditions as to construction, healthfulness, and any other phases of the tenement-house system that affect the public welfare. This committee has made an elaborate report. It went about its work in an intelligent manner, seeking through every possible avenue information upon the subjects referred to it for consideration. The questions considered and answered in the report have a vital lesson for every city of any considerable population, especially for those of commercial importance, for ports of entry, and wherever there is homed or housed a large foreign element.

While the local conditions affecting tenement-house life in New York may be somewhat unique, the same conditions, to a greater or less degree, exist in all great centers of population. In all our great commercial cities there are large foreign and native populations crowded into extremely narrrow limits. The report puts the facts strongly, and their truths will apply to Philadelphia as well as to New York:

"The personal observation of the committee and the testimony of numerous witnesses show that the over-crowding of the population, both as to house and district, has evil effects of various kinds; keeping children up and out of doors until midnight in warm weather because the rooms are almost unendurable; making cleanliness of house and street difficult; filling the air with unwholesome emanations and foul odors of every kind; producing a condition of nervous tension; interfering with the separateness and sacredness of home life; leading to the promiscuous mixing of all ages and sexes in a

single room, thus breaking down the barriers of modesty and conducing to the corruption of the young, and occasionally to revolting crimes."

The law must regulate these matters, they cannot safely be left to the landlords. In their greed for excessive rents, landlords would consent to crowding the rooms of their tenement houses with human beings layer upon layer. The law only, and that vigorously executed, can secure and regulate more favorable conditions for the future tenement house. It is startling to reflect that eight-fifteenths, or a little over one-half of the total population of the great city of New York, live in what are generally called tenement houses. This reckoning does not include the better class of rented houses. The death rate of these houses is very much higher than in single houses. Rear tenements are veritable slaughter houses of children. These are generally cut off from air and sunlight; the buildings old, dark and damp; decay and long occupancy have pervaded every nook and corner, have permeated their very walls with the seeds of disease.

One best known cause operating to increase the death rate, is density in population. One of the best means for minimizing the evils of overcrowding is by letting in more air and sunlight; this in the interest of both public health and public morals. This end can be served by numerous judiciously distributed and well arranged park spaces. Pure air and strong light render impossible many evil conditions. In the distribution of these rest, recreation, play-ground spaces, consideration should be given to the matter of their proximity to our public schools. These institutions for the development of vigorous men and women too often are destitute of room for recreation and healthful exercise. This is *criminal.*

Here in Philadelphia, we have, along the Delaware and Schuykill rivers, extensive shore lines; and it would be practicable and certainly greatly contributive to public health, comfort and pleasure, to have small parks connected with some of the many docks along the shores of these rivers. Thus supplying healthful conditions; letting in air and sunshine; furnishing places of rest and recreation for all classes, and breathing places and playgrounds for those who cannot often get out into our greater suburban parks. Such parks could be so located as not to interefere with commercial interests. In addition to the importance of these small parks as health requisites, as inlets of light and air, they would add greatly to the beauty of the city. Many sections along the rivers named are overcrowded; many of them are tenement localities with dense populations in need of breathing spaces, for men and women, and playgrounds for children. Nothing better could be supplied than the refreshing, healthful air of the rivers. "There is no reason in humanity why an enormous portion of our population should be permitted, year after year and generation after generation, to live without those alleviations which the health and comfort of the people require and civilization demands."

Such parks should be established with strict regard to local conditions; to system and science; to character of buildings, density and character of population

Further, where the population is densest there is the least personal, household and general cleanliness—the chiefest factor in promoting individual and public health. The principle obtaining in aseptic surgery should be given a more general application.

The importance of these facts are growing to be more fully realized. There is a growing demand for more municipal bath-houses. The basin or tub will no longer answer the demand. The report we refer to very strongly puts the case in relation to these baths:

"The freer use of water by the tenement house population would aid them very materially in their struggle for existence, by assisting the elimination from their systems of the poisons absorbed in the sunless and airless dwellings. That several hundred thousand people in the city have no proper facilities for keeping their bodies clean is a disgrace to the city and the civilization of the nineteenth century. These facilities have been used and are abundant in many enlightened nations, and they are being increased in every way possible. The amount of money annually spent for charity amounts to millions, and the question arises whether it be not greater economy to spend more for the preservation of health and the prevention of disease, because less would then be required for the support and care of the sick and helpless. The cultivation of the habit of personal cleanliness has a favorable effect, also, upon character; tending to self-respect and decency of life."

Dr. Albert Shaw states that municipal baths have been a great success wherever established in Europe.

"The public baths of Glasgow are six or seven in number, and have cost probably $600,000, or in round figures, $100,000 for each establishment. They contain great swimming tanks for men and women separately, and have every kind and sort of tub, shower and special baths, and offer very special inducements to school children. A small charge is made, school children in some of the towns not paying more than half a penny, one American cent, for a bath." These baths are so conducted as to make them nearly or quite self-supporting.

These questions are all of urgency, and should receive the prompt and enlightened consideration of state and municipal authorities. With greater precautions and wiser provisions for the public health, there will be less demand upon private and public charity, fewer drafts upon State and municipal treasuries for the support of public institutions. Economy, humanity, every consideration of the public welfare appeals to legislative and municipal authority to do more along the lines suggested and less to promote the enterprises of Professional Philanthropy.

PETITS SOINS.

A little care and effort on the part of mother or nurse will often give a child that chiefest beauty in a face, fine eyelashes. While the baby is asleep on the knees, if there is any tendency to inflammation or redness, she can softly bathe the eyelids with diluted witch-hazel, quite warm, or with a mixture of half a dozen drops of spirits of camphor with two teaspoonfuls of borax and four ounces of water. The borax, however, although exceedingly soothing and purifying, has a tendency to create dryness, and this has to be counteracted by rubbing in with very gentle motion some soothing and enriching ointment—cold cream, vaseline, mutton tallow, or even common lard that one has "tried" over one's self to make sure of its purity. This ointment should be applied very delicately, as it is apt to promote the growth of hair, and the hair is desired nowhere but on the brows and lids. Often when the lashes are thin and short, pale and irregular, showing little strength, a nightly application of vaseline will do them a great deal of good, the richness being absorbed by the capillaries, and reappearing in a longer and stouter growth of lash; and vaseline or some pure emollient oil rubbed at night along the brow will take out all stiffness from the shorter hair there, darken the color, and make the arch, which is often but half finished, more complete. Although in Colonel Higginson's *Malbone* some one suggests that Emilia's eyelashes are too long for anything but full dress, yet in truth no eye ever has a lash too long for beauty, the length and thickness and lustre of the lash giving shadow that means darkness, and lifting of the shadow that means brilliancy.—*Harper's Bazar.*

ABSTRACTS.

REPORT OF CASES OF OPIUM-POISONING SUCCESSFULLY TREATED BY PERMANGANATE OF POTASSIUM.

Dr. William Moor, of New York, (*Med. Record*, March 2, 1895) gives an account of some cases of opium-poisoning, which were reported to him, together with one occurring in his own practice.

CASE I., reported by Dr. T. S. Buist, of Charleston: "On February 13, 1894, at 12 M., I was called in haste to see a young woman (white), nineteen years of age, who had taken by accident one and a half ounces of laudanum. The poison had been taken at 10 A.M. The first medical aid arrived at about 11 o'clock. Condition upon my arrival: Pupils of both eyes contracted to the finest possible point, eyes dull and glassy, dropping of eyelids; insensibility to external impressions, pulse slow and intermittent, respiration slow and labored; almost utter inability to sustain the body upon the limbs. At once a hypodermic injection of one-sixteenth grain of atropine was given, and the result watched with the utmost interest. At the end of thirty minutes all symptoms were aggravated. I ordered as soon as could be procured: Potass. permang. gr. vj.; Aq. destill. ʒ j. At 12.45 I injected ten drops of this solution in the arm. In ten minutes the patient's locomotion improved. In fifteen minutes she spoke and begged to be allowed to sleep. Pulse stronger, respiration more regular. Allowed to rest in a chair for five minutes, profound sleep coming on. Patient aroused and ten drops of the permanganate solution introduced in the other arm. The effects in ten minutes were wonderful. Susceptibility of the pupils to light manifest, consciousness returned. Patient in fifteen minutes hysterical and crying; pulse, 76; respiration, 20 per minute. By six o'clock in the evening all symptoms had passed away and a complete recovery was the result."

CASE II., reported by Dr. Edwin De Baun, of Passaic, N. J.: "On March 3, 1894, at two o'clock in the morning I was awakened by a man who told me he had swallowed seven grains of morphine by mistake for quinine, a half hour before. While relating his experience at first he seemed very lucid, but on further questioning him his speech became thick and he began to sway from side to side, and implored me to be quick, as the drug was taking rapid effect. I told him to walk about the room, while I went to the inner office and prepared twenty grains of the sulphate of zinc in solution. On returning I found my patient on the floor on his hands and knees trying to keep his head from striking the floor. I raised him, gave him the sulphate of zinc, sat him on a chair and returned to the office for permanganate of potassium. I dissolved ten grains of it in half a glass of water, which only took a few minutes, and when I again returned to my patient, he was lying on his back on the floor, having fallen from the chair where I left him. I administered the permanganate solution, again raised him and placed him upon a chair where I could watch him, while I telephoned for Dr. A. C. Pedrick and sent for two policemen, who took the man into the open air. In the meantime the stomach-pump was made ready. After walking the man a short distance, he went so rapidly under the influence of morphine, that they were obliged to carry him back. We sat him on the back stoop and by this time Dr. Padrick arrived, and together we tried the time-honored stomach-pump, which, of course, did not work. We gave him twenty grains more of the sulphate of zinc, which did not act. In a few minutes the man was in a profound stupor, and nothing but the severest handling could arouse him, and then only to elict a groan, there being no voluntary motions. It was now impossible to administer any medication by the mouth. Therefore we determined to wholly rely on the efficacy of the permanganate of potassium, hypodermically. Three grains were administered by means of a two drachm aspirator, thinking that the more dilute the solution, the less irritating to the tissues.

The first hypodermic was administered one hour and a quarter after the morphine was taken; the second hypodermic in fifteen minutes, and the last hypodermic fifteen minutes later, using in all, hypodermically, nine grains, which made a total of nineteen grains. It was not until the last hypodermic that he showed signs of voluntary motion, and this was only evinced by raising his leg and scratching it. He soon regained consciousness, and was able to answer questions intelligently, although when left to himself each time would lapse into a sleeping condition, from which it was difficult to arouse him. He was taken into the house and one-half hour later was able to walk with the assistance of the two policemen. He was now walked to Dr. Pedrick's office, a distance of about five blocks, where he stayed during the remainder of the day, and made a rapid recovery."

The fact that the emetic did not act, and the stomach-pump did not work, and as it was impossible to either walk the man or arouse him by violent manipulations, shows conclusively that the permanganate of potassium must have saved his life.

Before reporting my own case I shall give an account of some animal experiments, the reason for which will be readily understood. As the reader has noticed, the permanganate in Case I. was administered only hypodermically. In a private letter which Dr. Buist directed to me he refers to some reports regarding animal experiments I undertook. Those reports were premature, and I must confess I was surprised when I heard of Dr, Buist's case and of other cases in which the antidote apparently was effective, even if given hypodermically. Still I remained sceptical and left it to comparative experiments to determine whether or not the much discussed chemical body had any antidotal virtues with regard to opium if administered hypodermically.

As to those premature reports alluded to, the simple truth about them is as follows: Having found that the antidote would select morphine in the presence of albumin and other organic matter, it came to my mind that this selective power would also manifest itself upon morphine which was held in solution by blood, the latter being principally a solution of albuminous matter in water, and that, therefore, intravenous injections of the antidote might be useful in cases of opium poisoning. In order to substantiate this idea I gave a good-sized rabbit a hypodermic injection of one grain of morph. sulph., followed in fifteen minutes by an intrajugular injection of three-fourths of a grain of potass. permang. (1 to 15), and sixteen minutes after this by another intrajugular injection of one-third of a grain of $Mn_2O_8K_2$. Two hours after the initial injection of morphine, the animal's respiration was 46 per minute, rising to 48 after three hours more.

Another rabbit of the same size also received one grain of morphine, but no intrajugular injection of permanganate. Thirty minutes later the animal's respiration was 14 to the minute and one hour after this only 12. Five hours after the injection of morphine the animal still breathed only 14 times per minute. The normal respiration of rabbits is 70 to 90 per minute. The intravenous injection of the antidote, therefore, was unquestionably of benefit to the animal thus treated.

To determine the value of hypodermic injections of permanganate in cases of opium poisoning, I used four good-sized rabbits, each weighing about three and one-half pounds (avoirdupois) — 1,585 grammes. By giving them hypodermic injections of morphine followed by injections of potassium permanganate, and at a subsequent period only injections of morphine, I was able to draw conclusions as to the value that hypodermic injections of the antidote would have on morphine that was absorbed into the circulation.

RABBIT I.—Received two grains of sulphate of morphine hypodermically at 9.22 A.M., March 1, 1894. Respiration extremely rapid, from fright. At 9.28 I injected four grains of $Mn_2O_8K_2$ in one drachm of water. At 9.32 respiration 120 per minute. At 9.45 the animal is semi-lethargic, but his ears are erect; breathing a great deal slower (50 per minute). After this his breathing gradually improved, being 64 at 10.12, and 60 at 10.22 A.M.; 10.26 A.M., injected two grains of potassium permanganate in one drachm and a half of water; 10.36 A.M., respiration, 76, semi-lethargic, ears erect; 11.15 A.M., respiration, 76; 12.40 P.M., respiration, 153; 1 P.M., respiration, 160; 1.25 P.M., respiration, 150; animal struggling vigorously if held suspended by the

ears, general appearance of the animal not lethargic; 2 P.M., power of locomotion begins to return; 2.30 P.M., locomotion much improved; 7 P.M., locomotion entirely restored; 11 P M., respiration exceedingly rapid, about 200.

March 2d, 8 A.M. The animal drinks water with avidity and takes food; is quite lively; respiration normal (95).

RABBIT I.—Injected two grains of morphine sulphate on March 4th at 1 P.M. At 2.45 P.M., the animal is in a completely lethargic condition; respiration, 26 per minute. At 3.25 P. M., slower, 22; 4.20 P.M., respiration, 21; 5.10 P.M., the same. At 5.50 P.M., the animal is still unable to move voluntarily, but breathes somewhat faster (24). At 7.45 P.M., the power of locomotion begins to return, breathing easier and quicker, being 70 per minute. At 11 P.M., the breathing is somewhat slower (62).

March 5th, at 8 A.M., the condition of the animal is about normal.

Thus we see that the administration of $Mn_2O_8K_2$ resulted in a decided improvement in the breathing and general condition of the animal. The difference between the results of the two experiments as regards the number of respirations per minute is certainly striking. The heart-action in these two instances and also in the following experiments did not offer any characteristics:

RABBIT II.—Injected on March 2d, at 9.14 A.M., two grains of sulphate of morphia. Respiration, 170; 9.18 A.M., animal is somnolent, lies flat on its abdomen, ears flat on the back; 9.20 A.M., repiration, 31; 10 A.M, respiration, 22; the animal is perfectly motionless if suspended by the ears; 10.8 A.M., injected three grains potassium permanganate (1 to 15); 10.16 A.M., injected three grains more of the potassium salt; 10.22 A.M., respiration, 32; 11 A.M , somewhat less (30); moves about at times; 12.15 P.M., breathing slow (16); 12.25 P.M., injected two and a half grains of permangante; 12.40 P.M., breathing improved (27); the animal struggles quite vigorously if held by the ears; is much less lethargic; moves about voluntarily; 12.50 P.M., respiration, 34; 1.20 P.M., animal moves about if put on the floor, power of co-ordination quite fair, tries to escape when approached; 1.45 P.M., breathing faster (38), regular; 2 P.M., respiration, 45, regular; locomotion normal; hardly any signs of lethargy; 9 P.M., respiration, 58, animal is quite lively, drinks some water.

RABBIT II.—Injected on March 6th, at 11.20 A.M., two grains of sulphate of morphia; 11.50 A.M., the animal is completely lethargic, eyes glassy, breathing slower (38); 12.43 P.M., respiration, 22; 1.30 P.M., still less (19); 4.30 P.M., respiration, 14; does not struggle if held up by the ears; 11.30 P.M., locomotion improved. The animal was found dead at 7.30 A.M., March 7th.

RABBIT III.—Injected two grains of sulphate of morphia on March 3d, at 8.20 A.M.; 9.55 A.M., completely lethargic; respiration, 20; 10 A.M., injected four grains $Mn_2O_8K_2$ (1 to 15); 10.20 A.M., respiration, 31; 10.27 A.M., injected four grains of the potasssium salt; 10.43 A.M., the animal is much less lethargic, moves about voluntarily, struggles vigorously when held by the ears; 11.13 A.M., respiration, 50; 2.30 P.M., much slower (26); 3 P.M., injected four grains potassium permanganate; 3.05 P.M., respiration, 30; 5.20 P.M., faster (47); 10 P.M., the animal is asleep, but the slightest disturbance will awake it; when held by the ears it struggles vigorously. Locomotion fair, showing perfect co-ordination; 10.20 P.M., the animal being disturbed ran fast a distance of sixteen feet.

March 4th, 8 A.M., the animal is quite lively and well.

RABBIT III.—Injected two grains of sulphate of morphia on March 6th, at 11.30 A.M.; 12.30 P.M., respiration, 200; 1.35 P.M., respiration, 48; 4.35 P.M., respiration 40; lethargic; 11.30 P.M., the animal breathes fast (90).

March 7th, 8 A.M., the rabbit is drowsy, but breathes very rapidly (130); 10 A.M., still drowsy; 3 P.M., same condition.

March 8th, 8 A.M., respiration labored (84), becoming more and more difficult and slow; 8.10 A.M., the animal is in extremis, has convulsions, shrieks peculiarly five or six times, dies at 8.15 A.M.

Thus rabbits II. and III. succumbed to two grains of morphine when no permanganate was used to antidote the morphine.

RABBIT IV.—March 6th, 12.30 P.M. Injected three grains of sulphate of morphia; 12.35 P.M., four grains of potassium permanganate; 12.40 P.M , respiration, 80; 12.55 P.M., respiration, 40; 1 P.M., semi lethargic; 1.05 P.M., four grains

$Mn_2O_8K_2$; 1.16 P.M., respiration, 42; 1.40 P.M., respiration, 35; locomotion fair; 2.50 P.M., respiration, 24; able to move voluntarily; 3.05 P.M., four grains potassium permanganate; 3.20 P.M., respiration, 32; 3.40 P.M., respiration, 40; 11.20 P.M., respiration 62; the animal is quite lively, locomotion perfect.

March 9th, 8 A. M., the animal is perfectly well; respiration 74.

RABBIT IV.—Recived an injection of three grains of sulphate of morphia on March 11th at 11.25 A. M.; 11.40 A. M., completely lethargic; respiration, 26; 1.15 P. M., respiration, 24; 4.45 P. M., respiration, 22; completely lethargic. At 7 P. M. the condition of the animal is greatly improved.

March 12th, 8 A. M.—Recovery complete.

A comparison of these last two experiments will show that the injection of the antidote were of decided benefit, inasmuch as they were always followed by improvement in the breathing and the general condition of the rabbit. From an unbiased consideration of the foregoing eight experiments I was justified in concluding that hypodermic injections of potassium permanganate are of great value in opium-poisoning. The question arises, how does the antidote act when thus administered?

When we consider, on one hand, the wonderful affinity of $Mn_2O_8K_2$ for morphia, and on the other hand, the rapidity of the circulation, it appears quite intelligible that the antidote should select the poison in question from among the albuminous ingredients of the circulating blood, and thus render it harmless. Of course, part of the permanganate will be deoxidized before it can enter the circulation but evidently enough of it is absorbed to accomplish its wholesome mission.

I relate a case of opium-poisoning which occurred in my own practice.

CASE III.—On April 6, 1894, at 8 A.M., I was sent for by Dr. Henry Altschul, of this city, to assist him in a case of morphine poisoning. On my way to the place I procured one ounce of a 1 to 15 solution of potassium permanganate (gr. xxxij. to ℥j. aq.). On arriving I found the patient, a young man of twenty-four years of age, in a condition of absolute insensibility, resembling a corpse. His face was livid; his pupils contracted to the size of a pin's point; his respiration—four times per minute—spasmodic and stertorous; his pulse slow, rather full. It was utterly impossible to arouse him or to make him react to any external impression. Dr. Altschul had been with the patient since 7 A.M., resorting to artificial respiration, injections of apomorphine, which produced no emesis, and giving strychnine and atropine hypodermically. As the patient was naturally unable to swallow, I sent to the nearest pharmacy for a medium-sized hard rubber catheter, also a piece of rubber tubing about one-half of a foot long, into which the catheter should fit, and for a glass funnel to fit into the rubber tubing. Meanwhile, in order not to lose time, and having in my mind the results of the animal experiments cited above, I gave the patient a hypodermic injection of 50 minims of the antidotal solution (3½ grains of potassium permanganate). This was at 8.30 A.M., half an hour after I was called. At 9 A.M. I administered 15 grammes of the original permanganate solution (16 grains of the antidote), diluted with a cupful of water. This I did by introducing through the patient's nose into his œsophagus the hard rubber catheter, which I had connected with the glass funnel by means of a piece of soft-rubber tubing, and by slowly pouring into the glass funnel the diluted antidotal solution as mentioned above. At 9.30 A.M., the patient's respiration had risen to eight per minute; but it was still impossible to arouse him. I therefore gave him another injection of 50 minims of the permanganate solution. A few moments later he gave the first evidence of returning locomotion power by violently tossing with his legs. Soon after this he began to show signs of returning consciousness. At 10.15 A.M. the patient could be made to walk with the assistance of two men. A few minutes later he cried bitterly, embraced and kissed his father, and answered rationally questions that were put to him by those present. Then he asked for black coffee and accepted a cigar, which he smoked vigorously and seemed to enjoy. By questioning him we found out that he had taken, at 6 A.M., one drachm of powdered opium, and for this purpose had filled thirteen gelatine capsules (No. II.) with the opium. We

found the empty drachm box at the place indicated by the young man.

At 11 A.M. I gave him seven or eight grains more of the antidote per os, and left him in my colleague's care. The next morning, April 7th, he was practically well and wanted to leave the house in order to make a business call.

Such a quick recovery after such a quantity of poison ingested—sixty grains of opium—and after a fatal issue had seemed almost inevitable is so remarkable that it fully justifies my claim set forth, that permanganate of potassium is the antidote par excellence for opium.

CASE VI., occurring in Pittsburg, Pa., reported through the kindness of Dr. Robert P. Finley, of Altoona, Pa.—Patient had taken three ounces of laudanum and was brought to the hospital in a moribund condition, three hours after having taken the poison. No reflex response, respiration four to the minute. As a last resort, after every other means had failed, eighteen and three-quarter grains of potass. permang. were given hypodermically, in the space of two hours and fifty-five minutes. In four hours from the first injection he was perfectly conscious, complaining only of sleepiness.

Up to this date I am cognizant of twenty-one cases of opium-poisoning, in which the therapeutic agent recommended by me as an antidote has been used with unmistakable success, although it is fair to assume that many other cases were not reported.

In the *Canadian Practitioner*, September, 1894, there appeared an able article from the pen of Professor Graham Chambers, of Toronto, in which he comes to the same conclusions I put forward in my original article on the subject. There is only one point on which my opinion differs from that of Professor Chambers. He says $Mn_2O_8K_2$, subcutaneously, is poisonous. Now I have shown that rabbits stood hypodermic injections amounting to twelve grains without any deleterious effect, and in the case reported by Dr. R. Finley (Case IV.), the patient had received nearly nineteen grains hypodermically. The mere fact that dogs are as susceptible to the action of manganese does not prove that $Mn_2O_8K_2$, given hypodermically in moderate doses to man, would have any toxic effect. Facts point to the contrary. I might state here that Dr. De-Baun's suggestion (see Case II.). to dilute the antidote for hypodermic use as much as possible, is an excellent one; one grain to one drachm of water seems to me a good proportion. Of course, for its use per os, it should be diluted in a much greater proportion, so as to bring in contact with it as much of the walls of the stomach as possible.* It might, perhaps, not be unimportant to emphasize once more, in order to avoid mistakes, that permanganate of potassium is not an antidote for all kinds of toxic substances. I have clearly demonstrated that it has absolutely no effect upon atropine, hyoscyamine, hyoscine, cocain, veratrine, pilocarpine, aconitine, that it could not be depended upon in strychnine-poisoning, in poisoning by oxalic acid and colchicum preparations. I have also shown that even after sixteen hours of contact, phosphorus was not oxidized by potassium permanganate. In connection with this it is highly interesting to know that "peroxide of hydrogen, with all its energetic oxidizing action, has no effect on phosphorus, a substance which is so readily oxidized by the air."

In addition to the foregoing, I found that $Mn_2K_8O_2$ has practically no effect upon muscarine and caffeine, especially in the presence of albuminous matter, and just a little oxidizing power over hydrocyanic acid, although, strange to say, it at once decomposes cyanide of potassium.

Eye-Strain a Cause of Nocturnal Enuresis.

Dr. George M. Gould reports a number of cases of children who were afflicted with nocturnal enuresis, that were cured by correction of the ocular defect by glasses. In most of the children the involuntary urination was accompanied by many other nervous symptoms, such as night terrors, headaches, chorea, etc., nearly all of which were also relieved or cured by glasses that corrected the visual anomaly. Some of the patients had undergone operations and treatment that had extended over years without relief of the trouble.—*Med. News.*

---

*It is now a well-established fact that the mucous membrane of the stomach secretes morphine which had been absorbed into the circulation, and that this secretion continues for many hours.

A MEDICAL VIEW OF MODERN FICTION.

The American Medico-Surgical Bulletin thus editorially discourses on this interesting subject:—

"Among physicians, 'The Heavenly Twins' is looked upon, not as a literary venture to be judged by artistic standards, but as a readable presentation of symptoms which suggest definite pathological conditions.

"'Ships that Pass in the Night,' is admirable as a pulmonary record, and 'The Yellow Aster' affords an insight into the psychic phenomena resulting from neglect of natural instincts and desires, which, surviving the appropriate period of life, subsequently assert themselves in the form of belated maternal love and *ex post facto* philoprogenitiveness.

"In the latter work, the mother of the heroine allows her children to grow up without receiving a single sign of maternal tenderness, but is overtaken before her death by a most singular form of retribution—a sudden and consuming desire for the society of babies and on overpowering craving to lavish upon children the accumulated stock of motherly love which had not found its appropriate and seasonable outlet. Most of the infants in the neighborhood being provided with mothers, who supply the required amount of caresses, the unfortunate woman dies of a plethora of pent-up baby-talk and unexpended maternal affection, but is happily given time to warn her daughter against a similar fate.

"As to Miss Harraden's book, while we find it useful in the profession for its glimpses into refined sick room conversation and pulmonary *persiflage*, we regret, from a medical point of view, that after giving such a careful history of the heroine's case, the author permitted her to be killed by an omnibus. It is humiliating, after following attentively the course of the disease and the method of treatment, to be dismissed without hearing the result of the autopsy. Moreover, we found her style so delightful that we would have gladly followed the hero to his last hemorrhage; but that, too, was denied us.

"Sarah Grand's cases are open to the same objection of incompleteness. She starts out enticingly with such a character, for instance, as Edith's husband, but leaves the later and more interesting phases of his pathological history untold. As a general rule, however, she comes up to the requirement of modern fiction; the case of most of her characters can be diagnosed; and with a little more clinical experience we have no doubt that her future novels will be above reproach. She will stand unchallenged as the novelist of venereal diseases, just as Du Maurier is first in the fields of hypnotic romance, and Beatrice Harraden in the department of laryngeal and pulmonary complaints.

"There is danger lest, in the first stages of the medical movement in literature, young writers will attempt to cover too wide a pathological area in their novels and forget the inexorable law of specialism that obtains in the medical profession itself. The specialistic tendency in medicine must prevail in medical fiction or the results will be unreliable and superficial. There are neurotic episodes in Mrs. Grand's otherwise consistently venereal work, which we cannot condone. To introduce a paretic or ataxic patient in a dermatological novel would not only destroy the unity of the story, but would justly expose the author to a suspicion of a want of thoroughness. If the writer has determined upon appendicitis as his plot, he should not waste his energies upon irrelevant diseases in his minor characters. He could gain variety by introducing other forms of enteric disorders, but should never exceed the limits of the abdominal region. Until he has had a thorough medical training, we think the course of a single disease should supply him with all the medico-literary material that he can handle in an intelligent manner. A blow on the head supplied the author of 'God's Fool' with all the plot that he needed; Ibsen's 'Ghosts' is simply the dramatization of an inherited brain disease; and many a successful short story is based upon a case of simple mania with delusions. There will be time enough for the combination of various ailments in a single work when each of the departments of pathology has its special novel. The task will then be easier because the author can gather the fruits of the labors of others; but, at present, there is no excuse for such a sacrifice of unity and thorough-

ness. We have no novel of the ear, no drama of the digestive organs, no romance of the kidneys, no pastels of the intestines; and these are only a few of the countless fields for literary and artistic honors.

"There are some who will sneer at this, as if the organs of the human body were unfit themes for artistic literary treatment. Ridicule will be thrown on the pioneers of the movement; of course, that is to be expected; but they will persist, nevertheless, and eventually succeed. Not only will the novel of the future contain an ever-increasing amount of medical material, but there are signs of a similar tendency in poetry. Anatomical verse is even now not uncommon, nor is it without serious intent, as is shown by the following stanza describing the mechanism of phonation:

"'The larynx now goes up;
The pharynx with a slam
Ejects the note
From out the throat
Pushed by the diaphragm.'"

AN HISTORICAL CASE OF DIPHTHERIA.

The influence which epidemic disease has had upon the course of history is a curious subject for speculation, but most of the instances which have been adduced by various writers who have occasionally touched upon the subject, have been instances of wide-spread epidemics, such as the plague at Athens, and the "Black Death" in England; but the effect which certain infectious diseases, more or less constantly present in temperate climates, may have had upon historical events is less clearly perceived. A curious instance is afforded by the death of Napoleon Charles, Prince Royal of Holland, the son of Louis, brother of Napoleon Bonaparte and of Hortense, his stepdaughter. This child died, when not quite five years old, of a disease, which, there can be little doubt, was diphtheria. The boy was a favorite of his imperial uncle, and was generally taken to St. Cloud when Napoleon stayed there in the summer. Though Napoleon never seems to have expressed himself clearly upon the subject, it was thought by many that he proposed to make this child, who was his nearest male relative in the second generation, his heir. Among those who shared this opinion was Meneval, who, as private secretary to Napoleon, had special opportunities of forming an opinion as to the Emperor's intentions. If this child had lived, Napoleon, Meneval thinks, would not have divorced Josephine; would not, therefore, have exposed himself to be insulted by the Emperor of Russia's refusal of the hand of a grand duchess; and, in all probability, would not have gone to Moscow, and might therefore, very possibly have founded a lasting dynasty. It is curious to remember that this boy's brother — his uterine brother at least — did actually sit on the throne of France. Napoleon, who was very much moved by the death of his nephew, offered a prize of 12,000 francs to the author of the best work on the means of preventing and curing croup. The boy died on May 5, 1807, and Meneval remarks that the superstitious looked upon it as a curious coincidence that Napoleon himself died on the same day of the same month fourteen years later.—*New Orleans Med. and Surg. Jour.*

Removal of Tatoo Marks.

For obliterating tatoo marks Dr. Variot pours on the marked spot a concentrated solution of tannin, and works it into the skin by series of pricks just as in tatooing proper. A certain quantity of tannin is thus introduced beneath the skin. He then rubs the part with nitrate of silver, and allows the solution of the salt to remain in situ until the prick marks show out as black points. The caustic is then wiped off, and the result is the formation of a black stain of tannate of silver. Inflammation is set up, and in the course of a fortnight scabs form, on the disappearance of which no trace is left of the original design, the only souvenir being a reddish scar, which in time becomes less visible. Various other plans had been tried without success, scarification, the introduction of opaque powders and caustics into the skin, etc. The tannin, in his operation, acts as a mordant and in no case did he have to deal with troublesome suppuration, although if the area be large it is well to do a piece at a time.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

IN THE BUFFALO MEDICAL AND SURGICAL JOURNAL

Dr. Herman Mynten reports

A Case of Nephrectomy.

The patient was a man 22 years old who for 17 years had attacks of pain in the back and left lumbar region, and symptoms of renal calculus. During the last five months the symptoms had increased, and the patient had night sweats, lost greatly in weight, had a poor appetite and slight dry cough.

Tenderness on pressure was great in the left lumbar region—less, though present in the right, and no tumor could be found by careful palpation.

Under cocaine anesthesia a successful cystoscopic examination was made and a mass of pus seen to exude from the unhealthy orifice of the left ureter, while the right was seen to be normal.

After stimulation for a couple of days with strychnia, whiskey, nutritive enemata, etc., nephrectomy was performed under chloroform anesthesia and a badly diseased kidney containing over a pint of pus was found and removed. After the escape of the pus the remaining part of the tumor weighed twenty eight ounces.

Two large calculi were found in abscesses in different parts of the structure.

As soon as the immediate shock of the operation passed away the patient began to improve.

Two weeks after the operation a fecal fistula showed itself, due to the adhesions which had existed with the colon; but this healed in a couple of weeks. Great gain in weight began, and about two months after the operation the patient resumed work in a machine shop.

The case is interesting not only on account of the successful result in a case which had progressed so far before operation, but because the diagnosis made by the cystoscope avoided the exploratory incision which otherwise would have been necessary.

Dr. Clayton M. Daniels reports

Two Peculiar Cases of Hernia.

In the first case an Italian laborer was struck a severe blow which caused a painful swelling in the groin. Examination showed an undescended testicle which was removed, the speumatic cord being stitched into the internal abdominal ring to occlude it. In the second case a woman had been subject for some time to an inguinal hernia and attempting to use a new truss was caused so much pain by it that the author was sent for, and found a prolapsed ovary, which he removed using the ovarian ligament to close the inguinal canal as before, and in this way he thinks obtaining a permanent cure.

IN THE BROOKLYN MEDICAL JOURNAL

Dr. Calvin F. Barber gives his experience with some

Fatal Cases of Chorea.

This disease he states is frequently regarded as one of no vital importance unless some organic lesion is to be discovered. Physicians frequently order some trifling treatment and dismiss the case as a trivial affection. The author has seen some fatal cases, and in one in which an autopsy was obtained could find no lesion to account for the symptoms. The percentage of mortality he thinks much higher than it is commonly thought to be.

Dr. Louis C. Ayer gives a summary of his observations in the

First Four Months of Diphtheria Cultures in Brooklyn.

The tubes provided were not in general demand at first, and the cultures were frequently improperly made, or their return delayed so much as to make a satisfactory diagnosis difficult or impossible.

The diagnosis made by the physician was correct in the majority of cases, but in a considerable percentage it was wrong, sometimes diphtheria being diagnosed when absent, sometimes vice versa. The importance of having an absolutely certain diagnosis in these cases is of course self-evident, and increasing interest in the subject is being steadily shown.

JOURNAL OF CUTANEOUS AND GENITO URINARY DISEASES.

Dr. James Bell reports

Two Cases of Syphilis, Etc.

These cases are given to add to our information on the period of communicability of this disease.

In the first case a man, in otherwise good health, contracted a chancre, and in about three months, when the secondary symptoms were well marked, was given systematic general treatment under which all symptoms disappeared in about three months.

The treatment was continued however for a couple of years and the patient married a few months later. Two months after his marriage his wife developed a chancre, and this was followed by constitutional manifestations, more than two and one-half years after their total disappearance in her husband

In the second instance a man ended a farewell supper to his bachelor friends by getting intoxicated and then contracting a chancre which, however, did not develop until several weeks after marriage. The wife had meanwhile become pregnant and was put on constitutional treatment, although she showed no symptoms of infection. At turn she was delivered of an apparently healthy child.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Contribution to the Study of the Ætiology of Rheumatic Affections of the Body Due to Tonsilar Diseases.

Dr. H. L. Wagner writes in the *N. Y. Medical Jour.:*

The tonsil has been justly termed by Gerhard a physiological wound—an inlet into the system guarded by leucocytes, which we have learned of late protect the body against the invasions of various microorganisms. If through inherited or acquired predisposition the energy of these leucocytes is diminished, or if the tonsil in a diseased state does not allow these corpuscles to migrate, then a soil may be given for infectious diseases, such as diphtheria, scarlatina, amygdalitis, etc.

The sequences which sometimes follow these diseases are important to observe—paralysis of various parts of the body after diphtheria, and also articular rheumatic affections following follicular amygdalitis. The results gained by clinical studies and bacteriological investigations in follicular amygdalitis, followed by rheumatic affections, are what I particularly desire to refer to.

The question which presents itself is, whether these rheumatic affections are produced by the germs (*Staphylococcus albus et aureus*, Fraenkel's pneumococcus, etc.) migrating from the tonsillar tissues into other portions of the body, causing rheumatism, or whether they remain in or about the tonsils, sending forth and distributing their ptomaines or poisonous products into the system.

The results of my investigations which I will give you in brief, show in follicular amygdalitis a migration of these germs, proving that rheumatism here is not caused directly by ptomaines.

Clinical observations show that the joints which are mostly in use are the ones generally affected; for instance the arytænoid cartliages of the larynx of singers (five cases), the knee joints of shoe dealers, owing to the constant kneeling posture (two cases), and the wrist joint of a violinist, (one case) and bookkeepers (two cases). Referring to the two cases above mentioned, where rheumatism of the knee joint developed, the bacteriological investigation showed that the synovial fluid obtained by tapping of the joint contained the same microorganisms as were found in the diseased tonsil. I was also able to identify the same germs in the urine of nearly all the cases. The family and clinical history of all these patients showed no signs of rheumatism before the attack of this tonsilar disease.

Absorptive Power of the Vagina.

Coen and Levi (*British Medical Journal*), have recently made some observations on the absorptive power of the vagina under various conditions of health and disease. Iodide of potassium is easily absorbed. If a tampon soaked with a 20 per cent. solution be introduced into the vagina, iodine can be found in the urine in an hour. The excretion reaches its maximum in twenty hours and ceases in forty-eight hours. Fever and pregnancy increase the absorption. Hysterectomy makes no difference. Iodoform is absorbed slowly and in very small quantities, but more if fresh than if old. Salicylic acid is absorbed quickly, appearing in the urine in one hour and disappearing in twenty-four hours. Salol is very readily absorbed. Antipyrine is excreted in an hour and a-half and is found for forty-eight hours, but its antipyretic action is feeble as compared with administration by the stomach. In brief, the vagina has undoubted absorptive power, and this is increased in pregnancy, in the puerperal state, and in pyrexia.

SURGERY.

Appendicitis.

Dr. Wyeth (*Medical Record*) says: "Given a surgeon of experience, a clean operator, who, with a minimum of traumatism to the intestines or contiguous viscera can remove a diseased appendix, and it would be better for exploratory laparotomy to be done in every instance within the first twenty-four hours of the disease. On the contrary, were I the subject of an attack, and not sure of my surgeon, I would keep flat on my back, quiet peristalsis and voluntary motion with morphine and take the chances of resolution, encapsulation by adhesion or rupture into the intestine. Good medical treatment gives the patient a better chance than a poor surgeon."

Pyoktannin in Epithelioma of the Ear.

The case described is one of epithelioma of the ear in which injections of pyoktannin caused a disappearance of the neoplasm. The left pinna was very prominent, had a large swelling in front of the ear, and the skin over the mastoid was adherent and discolored. Pyoktannin injections (one in five hundred, one in three hundred, and then one in one hundred) were used. The growth hardened and became more defined after two injections, and the pain was relieved. Death took place sixty-five days after the first injection, and at the post-mortem examination no epithelioma was found in the tissues in front of the ear.—*Dr. Wilkins in Brit. Med. Jour.*

Ruptured Gastric Ulcer Successfully Treated by Abdominal Section and Suture.

T. H. Morse (*Brit. Med. Journ.*) The patient, a young lady aged twenty, having had symptoms of gastric ulcer, was suddenly seized with pain, followed by faintness and vomiting. The pain, which was of a burning character, commenced over the region of the stomach, and gradually extended all over the abdomen. Abdominal section was performed nearly five hours after the commencement of symptoms; the contents of the stomach were found in the peritoneal cavity. The stomach was withdrawn, and a perforation found on the anterior surface close to the cardiac orifice. The organ was washed out and the perforation closed with Lembert's sutures; the stomach was returned, the peritoneal cavity washed out, and the wound united. No food was given by the mouth for sixty hours, and at the end of three weeks the patient was quite well. The author had not up to the present time seen a record of any other successful case of this kind in this country, though cases had been reported by Drs. Penrose and Dickinson, also by Mr. Gilord and Mr. Barling, and by Mr. Warrington Haward, references to which were to be found in the *Brit. Med. Journ.* of the past year.

Mr. Barwell, in the discussion, said that he had been able to find twenty-five cases on record of closing a rupture in the stomach wall, and there were at least four others. In one of the twenty-five cases there was a localized abscess close to the small curvature; this abscess was opened, and that was all that was found to be necessary. He then described Kriege's case. Mr. Barwell suggested the following points, which he thought might point the way to success: First, to operate as soon as possible; secondly, that the incision through the abdominal wall should be to the left of the middle line; thirdly, to search very thoroughly the front wall of the stomach, as in these cases the opening was for various reasons liable to be hidden by lymph, puckering, etc. He suggested that it might be advisable to introduce into the patient's stomach some colored fluid, such as coffee, for this purpose. He could not agree with Mr. Haward that it was necessary to cut away the margin of the ulcer before suturing the stomach. He thought that Mr. Morse had done very wisely in washing out the stomach, and also in eschewing antiseptics in washing out the peritoneum. Mr. Barwell had seen very good results in washing out the peritoneum with warm distilled water in restoring patients from collapse during abdominal operations.

Surgical Treatment of Pulmonary Cavities.

Dandridge maintains that tuberculous cavities in the lower portion of the lung, if single and superficial, should always be opened, provided the patient will allow the operation. Abscess, gangrene and hydatid cysts should be opened and drained when their position can be clearly ascertained. The cavities should be treated by packing with iodoform gauze. It must be ascertained that adhesion of the lung has taken place, and the most perfect surgical technique must be employed.

Aristol in Otorrhea and Burns.

Dr. Krebs, of Hildesheim, has found aristol—which is a di-iodide of thymol occurring as a brownish powder and containing nearly half its weight of iodine, and which has been used for the last three or four years in various skin diseases, ulcers, burns, keratitis and nasal affections—very valuable in aural practice. In thirty-three cases of chronic purulent otitis, aristol alone effected a complete cure in twenty-two. He does not consider it to be an antiseptic, as it does not deodorize a discharge, but he finds that it has a marked effect in drying up and arresting the secretion. In serous discharges of a chronic character persisting after the purulent character has disappeared aristol is preferable to all other drugs, and especially to boracic acid. Often one or two insufflations are sufficient to arrest the serous discharge. It is also of value in chronic otorrhea when uncomplicated and where the perforation is a large one; also in cases where there are granulations of the tympanic cavity and meatus, provided they are not too extensive, and that they are not due to caries of the bone. Aristol should not, however, be used where there is but a small perforation in caries, or where the mastoid antrum is affected, and it is useless in fetid otorrhea, though, if the fetor is due merely to want of cleanliness, the ear should be cleaned, and boracic acid, which is a true antiseptic, blown in. According to Dr. Haas, burns and scalds of all kinds are not satisfactorily treated by means of aristol, which is, chemically speaking, biniodide of thymol. His plan is to disinfect the burnt surface with a boracic lotion and to open the blebs; aristol gauze is then applied, and this is covered with sterilized cooton-wool, gutta-percha paper, and a bandage. He does not recommend the application of aristol in powder direct to the wound at the beginning, as this is calculated to hinder the dressing from soaking up the secretion. Later, however, when this has diminished, the aristol may be applied either in substance or in the form of a ten-per-cent. ointment made up with olive oil, vaseline and lanoline. Dr. Haas collected a large number of references to reports by continental and American surgeons on the use of aristol in burns, a treatment that is by no means very novel, as Dr. Stern, of New York, employed it successfully more than three years ago. He, and most of the writers referred to by Dr. Haas, employed a ten-per-cent. ointment or a solution of aristol in oil from the beginning. The great advantages of aristol are its analgesic action, its antiseptic properties, and its power of hastening cicatrization. Added to these, which to some extent are shared by iodoform, is another great advantage, viz., its entire harmlessness. In this it differs from iodoform, which is unsuitable for application over an extensive surface, for fear of its exerting a toxic action.—*The Lancet.*

The Antiseptic Treatment of Burns.

An eminent French surgeon recently concluded an article with the above heading in the following words:

1. Fresh, superficial burns, as well as deep ones, can heal under antiseptic treatment without the production of pus.
2. If pus is produced, the wound is disinfected, and the course remains the same as if non infected. But if the pus is of long standing and the wound begins to granulate, then disinfection is not possible.
3. To disinfect widespread burns an anesthetic will often be necessary, and to this end chloroform is best suited.
4. If the wound is non-purulent, the unnecessary use of an antiseptic hinders the healing process.
5. Antisepsis is the best analgesic.
6. Burns heal rapidly under the antiseptic treatment. Burns of the second degree require eight days; of the third degree, from two to three weeks.
7. Burns of the second and third degree heal without trace remaining; of the fourth degree, cause a scar, which does not retract, while this will be smoother the less the amount of pus.—*Charlotte Med. Journ.*

Surgical Tuberculosis.

For abscesses, ulcers and joint affections: Open freely, and excise if joint be involved. Remove the caseous material by curetting; sponge the parts well and arrest the bleeding. Fill the cavity, through a thick rubber tube, with salt solution kept at the boiling-point; fill and empty the cavity until it is thoroughly cauterized. Or, fill the cavity with a cold or lukewarm salt solution, and raise the liquid to a boiling-point by introducing into it the blade of a thermo-cautery at red heat. One minute is sufficient to heat the water in a cavity as large as a pigeon's egg. Do not touch the walls of the cavity with the blade of the knife. Give an anesthetic if necessary, though usually cocaine locally will be sufficient.—Jeannel, *Midi Medical.*

Internal Urethrotomy and Forcible Dilatation.

Cantalupo (*Brit. Mer. Jour.*) advocates internal urethrotomy in hard strictures where a dilator cannot be introduced, or, if introduced, cannot be opened (in which case he uses Maisonneuve's urethrotomy). The wound in internal urethrotomy is much less extensive than in forcible dilatation, and the dilatability of the stricture is much greater after urethrotomy than after divulsion. The chief dangers are: (1) Hemorrhage; this may be avoided by using small-bladed instruments—for example, Bottini's. (2) Extravasation of urine; best avoided by retaining a catheter of less calibre than the divided stricture, and using some drainage tube as a siphon. (3) Pyemia may be excluded by antiseptic measures. (4) Fever, generally due to local retention of pus. Cantalupo finds a fresh indication for internal urethrotomy in cases of chronic gleet with stricture, where, after dilating the stricture up to a certain point, it still cannot be dilated up to the calibre of the second part of the urethra.

A Bloodless Operation for Hemorrhoids.

Manley (Boston *Med. and Surg. Jour.*) describes his bloodless method of treating hemorrhoids. A brisk purgative is given the evening before the operation. Before operating, two to four ounces of whiskey are administered, and effective cocainization applied hypodermically. Anal dilatation, gradual and steady; without rupture of the muscle, is done, and, after drying and mopping with cocaine solution, each hemorrhoid is separately seized, close to its base, firmly between the tip of the thumb, index and middle fingers. It is put on full stretch, then twisted, and finally so completely crushed that it is reduced to a pulp, and none of the investing tunics remain, except the mucous membrane and its under stratum of fibrous tissue. The mass is then returned, and an opium suppository introduced. He has treated thirty-five cases in this way with perfectly satisfactory results.

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING MARCH 9, 1895.

The leave of absence for seven days granted Captain Paul Clendenin, Assistant Surgeon, is extended twenty-one days.

The Attending Surgeon at Boston, Mass., will attend the sick at Fort Warren, Mass., during the absence of Captain Clendenin.

1st Lieutenant George D. De Shon, Assistant Surgeon, is relieved from duty at Fort Logan, Colorado, and ordered to duty at Fort Douglas, Utah.

Captain Freeman V. Walker, Assistant Surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at Fort Trumbull, Conn.

Leave of absence for six months, on account of sickness is granted 1st Lieutenant Frank T. Meriwether, Assistant Surgeon, U. S. Army.

CHANGES IN THE U. S. ARMY FROM FEBRUARY 16, 1895, TO FEBRUARY 28, 1895.

Carter, H. R., Surgeon: To assume temporary command of Cape Charles Quarantine during absence of P. A. Surgeon: T. B. Perry, February 27, 1895.

Kalloch, P. C., Past Assistant Surgeon. Directed to rejoin station Cincinnati, Ohio, February 21, 1895.

Perry, T. B., Past Assistant Surgeon: To proceed to Brunswick, Georgia, Quarantine, for temporary duty, February 27, 1895.

Houghton, E. R., Past Assistant Surgeon: Granted leave of absence for ten days, February 18, 1895. Leave of absence extended five days February 22, 1895.

Blue Rupert, Assistant Surgeon: To proceed to San Francisco, California, for duty February 23, 1895.

ORIGINAL ARTICLES.

INJURIES OF THE VERTEBRAL COLUMN AND SPINAL CORD AND THEIR TREATMENT.*

J. C. BIDDLE, M.D., Fountain Spring, Pa.

In the selection of my subject for this paper I do so because I am led to believe that the injuries to the bony structure of the vertebral column and the spinal cord have not received the attention at the hands of the surgeon that their importance demands. The brain, uterus, ovaries and, now that important organ, the appendix, each have received respectful attention, since the introduction of the aseptic or antiseptic treatment of wounds. The inordinate impetus, the brilliant successes achieved in operative surgery during the last few years must place the treatment of injuries of the vertebral column and spinal cord upon an entirely new basis.

The operation of laminectomy for an injury to the vertebral column was first performed by a young surgeon named Henry Kline, at St. Thomas Hospital, London, June 16, 1814, at the suggestion of Sir Astley Cooper. The patient died three days after the operation and the surgeon believed he had hastened the fatal termination by the operation. The operation is still held by many surgeons to do positive injury, because of the difficulties which attend its performance. The operation has been performed, however, many times, and by the most eminent surgeons of Europe and America. They have, however, met with little success.

My experience has taught me that operations on the vertebral column are attended with as good results as those upon the brain or abdomen when you take into consideration the nature of the surroundings. We remove portions of the alimentary canal and large areas of brain substance without any apparent inconvenience or discomfort to the patient. Where is there a record of a case with total destruction of a part of the spinal cord and complete recovery has taken place? It is therefore manifest that the cord, as a whole, is of more importance, and is more intricate than either brain or alimentary canal and we should not expect the same percentage of recoveries, or say that the operation of laminectomy has not its utility in a certain number of cases. It is my opinion that in all cases of dislocation with extreme displacement of the vertebral column, or in fracture dislocations where the cord has been crushed or lacerated, the injury is irreparable. This is to say that the spinal cord is incapable of regaining or of repairing any extensive

* A paper read before the Lehigh Valley Medical Association, at Easton, January 31, 1895. From advance sheets of the "Lehigh Valley Medical Magazine."

lesion. But how can you determine which cases will and which cases will not recover? I am clearly of the opinion that the only way to answer the question immediately is to make an exploratory incision in the cases where paraplegia exists. The vertebral column is so thickly covered by muscles, especially in the lower dorsal and lumbar region, that it is generally impossible to detect the usual symptoms which we find in fractures of the long bones—crepitation and preternatural mobility. Deformity or displacement may exist without making sufficient pressure to produce paralysis because of the large caliber of the vertebral canal. Again we should not attempt to elicit these signs for fear of adding to the existing injury. By making an incision and approaching the parts carefully no harm can occur. Just in the same manner as we would make an irreducible simple fracture of the long bones a compound one and be able to adjust the deformity accurately.

This procedure has several advantages. By the exploratory incision you are certain as to the amount of injury. The spines of the vertebra should be removed near the seat of the injury thereby preventing pressure upon the bed and producing exhausting bed-sores. Again, you give the extravasated blood the opportunity of escaping and, in this way, prevent a possible abscess which would be certain to take the life of the patient. The only objection to this, which would be, by some surgeons, considered a radical and unwarranted procedure, is the shock attending the etherization and operation. Out of fourteen cases operated upon by myself since September, 1890, for fracture or dislocation with total paraplegia, shock has not added to the number of deaths or hastened the otherwise fatal termination. I am firmly convinced that the chances for recovery are diminished in waiting for nature to effect a cure. When there is bone pressure, why not remove it at once? In injuries below the first lumbar vertebra to the cauda equina I would be inclined to wait until after the acute symptoms had passed away, say a week or ten days, and then, if no improvement was manifest, I would operate. Even here why trust too long to the capacity for regeneration when there is great and constant danger of total destruction by the slightest movement of the body? Here, if the nerve be completely separated by the injury and bone or ligaments be interposing they can be removed and the nerve brought together by suture if necessary. We all know that complete division and separation of nerve is no barrier to its recovery but it must have an opportunity to unite and it is plainly our duty to put it in a proper position for nature to establish the reunion.

From my position then I will not sum up or conclude, as has been done in the past by all authors and surgeons, that "the operation of laminectomy for traumatic lesions, as compared with the condition which it is intended to relieve, should be abandoned because *a priori* argument and the results of published cases show that it is unlikely to be of service." I take it that this conclusion is absolutely wrong. It is true that the recoveries recorded by such surgeons as Erichsen, Hutchison, Leyden, Bryant, Macewen, Thorburn, Abbe, and others, are not such as would enthuse or inspire confidence in a conservative and conscientious surgeon. It is a wonder that the operation has not inspired some one who desires to cut and saw for a living or one who was trying to make a record for himself like the fast disappearing ovary fiend and now the appendix surgeon who can smell the cause of an appendicular colic (?).

The diagnosis then in my manner of procedure is not a matter of inference. You will know that the paralysis is due either to bone-pressure, an intra-thecal hemorrhage or perhaps an extensive laceration, crushing or causing a total separation of the cord. If you were convinced beyond a reasonable doubt from the symptoms, that the paralysis was due to a clot you would not be justified in operating. From the cause then you must deduct, in a great measure, your conclusion for surgical interference in cases which are suffering with paraplegia.

The symptoms of dislocation with extreme displacement and those of fracture of the vertebral column with injury to the cord are so manifest that I need scarcely take your time in describing them.

In the time of my service at the hospital 110 cases of severe injuries to the vertebral column have come under my notice and were divided as follows:

Fracture dislocations	12
Fractures	44
Dislocations	23
Partial dislocations	31

On the 12 fracture dislocations, 9 or 75 per cent. died, 2 were improved, and one unimproved. These were treated 966 days.

Of the 44 fractures, 25 or $56\frac{9}{11}$ per cent. died, 10 recovered, 5 were improved, and 4 were unimproved. These were treated 4,580 days.

Of the 23 dislocations, 6 or $26\frac{4}{13}$ per cent. died, 7 recovered, 8 were inproved, and 2 were unimproved. These were treated 3,810 days.

Of the 31 partial dislocations, 1 or $3\frac{3}{11}$ per cent. died, 16 recovered, 12 improved, and 2 were unimproved. These were treated 3,909.

The medical treatment in these cases consists in keeping the patient at complete rest, with the upper portion of the body elevated, especially if the injury be in the cervical or dorsal region. The bowels should only be moved when positively necessary, and then only by enemas; brisk cathartics should seldom be given. A soft catheter should be used about every four hours so as to keep the bladder empty. Great care should be taken so as not to infect the bladder. When cystitis occurs, the bladder should be carefully washed out twice a day with a saturated solution of boracic acid and then again with a solution of ten grains to the ounce, or a one to sixty solution of creolin. Quinine in five-grain doses four times a day until the physiologic effects are complained of; stimulants, tri-nitrin and digitalis with brandy are given until shock disappears; this may last from two to even five days. Morphine and paraldehyde should be administered hypodermatically to allay pain, and after the shock has disappeared, thirty grains of chloralamid, or twenty grains of potassium bromid and five grains of chloral hydrate should be given frequently enough to procure sleep. The patient should be kept perfectly dry and clean and his back dusted with europhen aristol. The patient should not be turned upon his side during the first four or five weeks. He should be raised when necessary by two attendants, one at his shoulders the other at his legs and lift him by pulling in opposite directions; if the patient be very heavy they can be assisted by two in the middle.

Of the fourteen severe cases operated upon since September 8, 1890, ten had the spinal cord completely or partially severed or crushed, and death was inevitable. In the remaining four the cord was compressed. Of these latter four, two have recovered so as to be able to perform manual labor, one following the avocation of that of a huckster, the other a nurse. The remaining two are still under treatment and much improved.

To illustrate our subject let me present to you a brief synopsis of three of the cases coming under my personal treatment.

In case 49* (the first recovery) there was a partial dislocation of the ninth dorsal vertebra. There was complete motor and sensory paralysis of the legs below the knees, but some slight motion and sensation of the muscles of the thighs remained. There was complete paralysis of the bladder and rectum, and extensive bed-sores at the point of fracture and on the sacrum. The patient was very much exhausted from pain, sleeplessness and cystitis, as he had sustained the injury three months before his admission. The urine was purulent and fetid. The patient was prepared for the operation and an incision was made extending from the seventh to the eleventh dorsal spine. The spinous processes of the eighth, ninth, tenth and eleventh vertebræ were removed and the laminæ of the eighth, ninth and tenth. The cord was found to be compressed between the ninth and tenth dorsal vertebræ. The pressure was removed by cutting the bone away. The sharp edge anterior to the cord due to the luxation was cut away and the cord thus freely liberated; the wound was closed in the usual manner and healed kindly. The bed-sores, too, soon disappeared and the patient made a good recovery, being in the hospital one hundred and eight (108) days from the time of the operation.

In case No. 56† the symptoms were about the same with the addition of profound shock, he being admitted a few hours after the injury. Upon making an exploratory incision a short time after his reception, the cord was found to be completely separated between the ninth and tenth dorsal vertebræ. He survived but ten days.

---

* See Appendix.
† See Appendix.

In case No. 67†, that of Thomas M., aged nineteen years, admitted May 8, 1891, it was found, after an exploratory incision, that he had sustained a fracture of the eleventh dorsal vertebra by being struck with the sharp corner of the oil-box of a car. The laminæ were found to be driven in making compression upon the cord. The laminæ of the tenth, eleventh and twelfth vertebræ, with the spines of the ninth, tenth, eleventh and twelfth were removed and the symptoms of paralysis, which had existed, soon began to improve and, at the end of 231 days after the operation, he had sufficiently recovered to walk without the aid of crutches and, with the exception of some slight paralysis of the posterior muscles of the thighs, made a good recovery.

And now let me say in conclusion, that here undoubtedly remains an extensive field for thought and experiment. Much has been written upon the subject by both physiologists and surgeons; but of what value are theories, if, after all, we cannot show, by a successful practice, that our theory has been more than a vague suspicion or a mere notion. If anything does inspire confidence in a surgeon for successful work, surely it must be that incentive arising, not out of a mere belief, but rather out of that experience in which belief has been transformed by observation and experiment into positive knowledge. I believe the subject I present to you today to be a most vital one. We all know the delicate and peculiar construction, not to say exclusive nature of the spinal cord, and the delicacy of operations connected therewith; and yet the rapid strides made in surgery during the last ten years teaches us that all knowledge is not yet gained in our science any more than that of other professions. In fact our eyes have been opened to such an extent that we often feel like using the words of the immortal Shakespeare—

"There are more things in heaven and earth, Horatio,
Than are dreamt of in our philosophy."

Undoubtedly right here is opened up a wide field for the inquisitive mind. I do not hesitate in saying that, were it not for the conservative position I previously held in regard to laminectomy, and the adverse conclusions of our best surgeons, out of one hundred and ten (110) cases, with forty-one (41) deaths, that have come before me during the last eleven years, more lives might have been saved.

†See Appendix.

APPENDIXES.

I.

DETAILS OF THE 110 CASES.

Case 1.—J. R., admitted to the hospital, December 10, 1883, fracture dislocation of 11th dorsal, died 2 months after being discharged, in hospital 298 days.

Case 2.—V. K., admitted January 9, 1884, fracture dislocation of 10th dorsal, died 4 months after being discharged, in hospital 118 days.

Case 3.—J. W., admitted January 10, 1884, fracture dislocation of 12th dorsal, died 3 days after admission.

Case 4.—J. W., admitted March 10, 1884, partial dislocation of 10th dorsal, in hospital 202 days.

Case 5.—J. S., admitted May 15, 1884, ancient partial dislocation of 10th dorsal, (3 years ago,) not benefitted, in hospital 31 days.

Case 6.—J. O., admitted June 30, 1884, partial dislocation of either 10th or 11th dorsal, in hospital 100 days.

Case 7.—A. H., admitted July 31, 1884, partial dislocation of 11th dorsal, improved, now a chronic invalid, in hospital 32 days.

Case 8.—E. F., admitted August 2, 1884, fracture dislocation of 10th dorsal, died 31 days after admission.

Case 9.—P. M., admitted September 17, 1884, dislocation of either 7th or 8th dorsal, in hospital 145 days.

Case 10.—P. C., admitted October 20, 1884, partial dislocation of 10th dorsal, in hospital 118 days.

Case 11.—M. O., admitted June 4, 1885, fracture of 11th dorsal, died 202 days after admission.

Case 12.—W. C., admitted October 10, 1885, fracture dislocation of either 10th or 11th dorsal, died 12 days after admission.

Case 13.—J. K., admitted December 5, 1885, fracture of 1st lumbar, in hospital 158 days,

Case 14.—G. B., admitted February 20, 1886, fracture dislocation of 11th dorsal, died in 2 weeks after leaving the hospital, in hospital 368 days.

Case 15.—J. M., admitted March 18, 1886, dislocation of either 11th or 12th dorsal, in the hospital 410 days.

Case 16.—E. A., admitted April 19, 1886, dislocation of either 9th or 10th dorsal, unimproved, in hospital 316 days.

Case 17.—J. N., admitted April 19, 1886, partial dislocation of 7th dorsal, in hospital 37 days.

Case 18.—D. S., admitted July 1, 1886, partial dislocation of 11th dorsal, chronic invalid, in hospital 37 days.

Case 19.—J. E., admitted July 26, 1886, dislocation of either 8th or 9th dorsal, slightly improved, in hospital 232 days.

Case 20.—T. C., admitted September 7, 1886, fracture dislocation of 11th dorsal, died 28 days after admission.

Case 21.—R. F., admitted September 7, 1886, partial dislocation, died about 6 months after leaving the hospital, in hospital 136 days.

Case 22.—J. B., admitted October 1, 1886, partial dislocation of 6th or 7th dorsal, in hospital 317 days.

Case 23.—J. C., admitted November 10, 1886, partial dislocation of either 7th or 8th dorsal, in hospital 145 days.

Case 24.—J. R., admitted November 13, 1886, partial dislocation of 1st lumbar, in hospital 90 days.

Case 25.—J. K., admitted December 14, 1886, partial dislocation of either 2nd or 3rd lumbar, in hospital 127 days.

Case 26.—F. F., admitted March 10, 1887, fracture dislocation of 1st lumbar, in hospital 110 days.

Case 27.—E. T., admitted August 25, 1887, fracture dislocation of 10th dorsal, in hospital 135 days.

Case 28.—A. S., admitted October 13, 1887, partial dislocation of 11th dorsal, died 205 days after admission.

Case 29.—M. B., admitted October 18, 1887, fracture of 11th dorsal, in hospital 140 days.

Case 30.—M. M., admitted February 15, 1888, fracture of 10th dorsal, died 1 day after admission.

Case 31.—M. M., admitted October 8, 1887, partial dislocation of either 6th or 7th dorsal, partial paraplegia remaining, in hospital 317 days.

Case 32.—O. G., admitted February 21, 1878, partial dislocation 10th dorsal, unimproved, removed by his friends in 6 days.

Case 33.—J. P., admitted March 3rd, 1888, fracture of 1st lumbar, died 146 days after admission.

Case 34.—N. S., admitted April 4th, 1888, fracture of 1st lumbar, died 71 days after admission.

Case 35.—J. M., admitted May 18, 1888, partial dislocation of 10th dorsal, in hospital 18 days.

Case 36.—P. F., admitted June 26, 1888, fracture of either 9th or 10th dorsal, died 11 days after admission.

Case 37.—A. F., admitted June 26, 1888, fracture of 3rd dorsal, died on day of admission.

Case 38.—A. E., admitted August 1, 1888, fracture of 1st lumbar, died 71 days after admission.

Case 39.—F. S., admitted August 5, 1888, fracture of 10th or 11th dorsal, died 24 days after admission.

Case 40.—J. M., admitted August 23, 1888, partial dislocation of 2nd lumbar, in hospital 76 days.

Case 41.—J. S., admitted October 16, 1888, fracture of 10th dorsal, died 3 days after admission.

Case 42.—F. D., admitted October 27, 1888, fracture of 1st lumbar, died 10 days after admission.

Case 43.—J. M., admitted January 20, 1889, fracture of 3rd cervical, died 1 day after admission.

Case 44.—J. M., admitted March 14, 1889, partial dislocation of 7th dorsal, improved, in hospital 35 days.

Case 45.—J. A., admitted March 21, 1889, fracture of 10th dorsal, died on day of admission.

Case 46.—P. G., admitted March 29, 1889, fracture dislocation of either 11th or 12th dorsal, died 2 days after admission.

Case 47.—T. K., admitted May 12, 1889, fracture of 10th dorsal, died 120 days after admission.

Case 48.—J. G., admitted May 12, 1889, dislocation of either 2nd or 3rd lumbar, in hospital 298 days.

Case 49.—E. E., admitted June 17, 1889, partial dislocation of 9th dorsal, in hospital 189 days.

Case 50.—N. P., admitted July 2, 1889, fracture of either 4th or 5th lumbar, in hospital 138 days.

Case 51.—G. W., admitted August 2, 1889, fracture of 11th dorsal, died 38 days after admission.

Case 52.—T. J. admitted November 25, 1889, partial dislocation of 1st lumbar, in hospital 84 days.

Case 53.—R. J., admitted November 28, 1889, dislocation of either 8th or 9th dorsal, in hospital 138 days.

Case 54.—S. K., admitted December 5, 1889, fracture of 1st or 2nd lumbar, in hospital 147 days.

Case 55.—F. S., admitted December 20, 1889, fracture of 9th dorsal, died 16 days after admission.

Case 56.—B. H., admitted January 31, 1890, fracture of 9th dorsal, died 10 days after admission.

Case 57.—J. B., admitted April 25, 1890, fracture of 9th dorsal, died on day of admission.

Case 58.—A. M., admitted May 10, 1890, dislocation of 11th dorsal, improved, in hospital 225 days.

Case 59.—F. M., admitted June 14, 1890, fracture of 10th dorsal, improved, in hospital 301 days.

Case 60.—S. W., admitted July 21, 1890, partial dislocation of 11th and 12th dorsal, in hospital 31 days.

Case 61.—A. A., admitted March 6, 1891, fracture of 3rd and 4th lumbar, died on day of admission.

Case 62.—J. M., admitted March 10, 1891, fracture dislocation of 2nd lumbar, died in 592 days after admission.

Case 63.—M. G., admitted March 19, 1891, partial dislocation of 11th and 12th dorsal, improved, in hospital 109 days.

Case 64.—W. H., admitted March 28, 1891, fracture of 3rd and 4th dorsal, unimproved, in hospital 85 days.

Case 65.—W. L., admitted April 13, 1891, fracture dislocation of 11th dorsal, died 111 days after admission.

Case 66.—P. D., admitted April 29, 1891, fracture of 9th dorsal, died 10 days after admission.

Case 67.—T. M., admitted May 8, 1891, fracture of 11th dorsal, total paraplegia except slight motion and sensation of posterior muscles of thighs, in hospital 231 days.

Case 68.—A. B., admitted June 28, 1891, partial dislocation of either 2nd or 3rd lumbar, slight paralysis, in hospital 83 days.

Case 69.—M. B., admitted June 28, 1891, fracture of 8th dorsal, slight paralysis remaining, in hospital 47 days.

Case 70.—J. C., admitted June 29, 1891, comminuted fracture dislocation of 1st lumbar, cord almost separated, died 35 days after admission.

Case 71.—A. G., admitted August 5, 1891, partial dislocation of 11th dorsal, improved, in hospital 95 days.

Case 72.—J. B., admitted August 11, 1891, fracture of 10th and 11th dorsal, died on day of admission.

Case 73.—M. H., admitted November 19, 1891, partial dislocation of 2nd lumbar, in hospital 322 days, improved.

Case 74.—C. K., admitted November 30, 1891, dislocation of 12th dorsal, died 565 days after admission.

Case 75.—J. M., admitted December 3, 1891, dislocation of 11th dorsal, died 87 days after admission.

Case 76.—J. G., admitted April 21, 1890, partial dislocation of 5th dorsal, in hospital 24 days.

Case 77.—A. C., admitted May 8, 1890, fracture of 10th dorsal, died 4 days after admission.

Case 78.—J. A.. admitted June 30, 1890, partial dislocation of either 2nd or 3rd lumbar, in hospital 11 days.

Case 79.—S. S., admitted March 3, 1892, partial dislocation of 12th dorsal, improved, in hospital 92 days.

Case 80.—A. A., admitted April 7, 1892, dislocation of 10th dorsal, died 3 days after admission.

Case 81.—J. L., admitted May 6, 1892, partial dislocation of either 1st, 2nd, or 3rd lumbar, improved, in hospital 23 days.

Case 82.—J. C., admitted June 20th 1892, partial dislocation of either 4th or 5th dorsal ancient, improved, in hospital 26 days.

Case 83.—C. B., admitted June 22, 1892, fracture of 8th dorsal, died 4 days after admission.

Case 84.—J. L., admitted August 10, 1892, dislocation of 10th, 11th, and 12th dorsal, died 24 days after admission.

Case 85.—J. S., admitted October 18, 1892, dislocation of 10th and 11th lumbar, in hospital 180 days.

Case 86.—B. S., admitted October 27, 1892, fracture of 12th dorsal, improving, remaining in hospital.

Case 87.—F. W., admitted November 7, 1892, fracture dislocation of 10th dorsal, died 5 days after admission.

Case 88.—W. R., admitted December 12, 1892, dislocation of 10th dorsal, improved, in hospital 320 days.

Case 89.—G. R., admitted February 8, 1893, fracture of 9th dorsal, died 77 days after admission.

Case 90.—J. B., admitted April 1, 1893, dislocation of 9th, 10th, and 11th dorsal, improved, in hospital 65 days.

Case 91.—C A., admitted April 18, 1893, dislocation of last dorsal and 1st and 2nd lumbar, improved, in hospital 421 days.

Case 92.—J. M., admitted August 12, 1893, fracture dislocation of 10th dorsal, died 19 days after admission.

Case 93.—J. Z., admitted August 13, 1893, partial dislocation of 9th dorsal, cord was compressed, in hospital 19 days.

Case 94.—J. C., admitted October 9, 1893, fracture of 12th dorsal, improved; in hospital 61 days.

Case 95.—A. G., admitted October 12, 1893, fracture of 1st lumbar, improved, in hospital 235 days.

Case 96.—J. H., admitted October 29, 1893, dislocation of 3rd lumbar, improved, remaining in hospital.

Case 97. —J. B., admitted November 13, 1893, partial dislocation of 9th dorsal, in hospital 93 days.

Case 98.—A. M., admitted November 23, 1893, fracture dislocation of 1st lumbar, died 33 days after admission.

Case 99.—G. Z., admitted January 12, 1894, fracture of 12th dorsal, in hospital 314 days.

Case 100.—J. F., admitted March 1, 1894, fracture dislocation of 2nd lumbar, remaining in hospital, able to walk with crutches, improving.

Case 101.—J. B., admitted April 11, 1894, fracture of 3rd lumbar, in hospital 119 days.

Case 102.—C. S., admitted June 12, 1894, partial dislocation of 4th dorsal, in hospital 6 days, removed to his home.

Case 103.—P. G., admitted June 27, 1894, partial fracture of 12th dorsal, in hospital 42 days.

Case 104.—H. A., admitted June 30th, 1894, fracture of the arches of the 11th and 12th dorsal, and the spinous processes of the 1st and 2nd lumbar, total paralysis below the knees, remaining in the hospital.

Case 105.—J. F., admitted September 21, 1894, fracture of 9th dorsal, died on day of admission.

Case 106.—E. B., admitted October 5, 1894, partial dislocation of 10th dorsal, remaining in hospital.

Case 107.—D. L., admitted October 26, 1894, partial dislocation of 5th dorsal, remaining in hospital.

Case 108.—J. C., admitted November 22, 1894, fracture dislocation of 10th dorsal, died 7 days after admission.

Case 109.—J. C., admitted December 12th, 1894, partial dislocation of 5th dorsal, remaining in hospital.

Case 110.—A. N., admitted January 8, 1895, fracture dislocation of 11th dorsal, died on day of admission.

II.

SYNOPSIS OF CASES OPERATED UPON.

Symptoms Before the Operation.	Nature of the Operation and Extent of the Injury to the Cord and Vertebral Column, and Results.
No. 1. Operated on Sept. 8, 1890. Thomas K., aged 35, a miner by occupation, injured Jan. 25, 1890. Had a fracture of the left thigh and a fracture of the 5th, 6th, 7th, 8th, 9th and 10th ribs. I saw the patient in consultation a few hours after the accident. Was in profound shock. Face dejected and showing extreme anxiety. He came to the hospital 3 months after the injury was received. Thigh and ribs united. There was complete paraplegia from just below the umbilicus in front and from the nates behind. There were extensive bed-sores both in the lumbar region and at the point of injury. He had cystitis and orchitis. Very much emaciated. Respiration frequent and shallow. He had some hypostatic pneumonia.	An incision was made extending from the 8th to the 12th dorsal. Very little hemorrhage. Ether was used as an anesthetic. The spines of 9th, 10th, 11th and 12th, with the arches of the 10th and 11th were cut away. A fracture was found with extreme displacement of the vertebral column. The cord was completely severed. Its cut ends being two and one-half inches apart. Wound healed. Died 3 weeks after the operation.
No. 2. Operated on Sept. 8, 1890. Evan E., aged 21, mine laborer by occupation. Complete motor and sensory paralysis below the knees. Some slight motion and sensation of the thighs. Paralysis of the spincters. Bed-sores, cystitis, urine purulent and fetid. Injured 3 months before his admission.	An incision was made extending from the 7th to the 11th dorsal spine. The spinous process of the 8th, 9th, 10th and 11th, and the laminæ of 8th, 9th and 10th were removed. Cord was compressed. Wound healed kindly and the patient improved rapidly. Torsion and hot water were used to arrest the hemorrhage. Recovery.
No. 3. Operated on Dec. 20, 1890. Frank S., aged 20, railroad brakeman by occupation. Complete paraplegia, severe shock, feeble, rapid respiration, high temperature.	Spines of 8th, 9th, 10th and 11th with the laminæ of the 9th and 10th were removed. Fracture of the 9th dorsal. Cord completely separated. Died 16 days after his admission.
No. 4. Operated on Jan. 31, 1891. Benjamin I. H., aged 33, miner by occupation. Paraplegia absolute as high as the umbilicus, shock severe, excruciating pain at the point of injury, high temperature, rapid, feeble pulse.	Operation same as in former cases. Comminuted fracture. Cord and membranes completely separated. Pain relieved, I think because the peripheral nerves from above the fracture were liberated. Died 10 days after his admission.
No. 5. Operated on Mar. 10, 1891. Joseph M., aged 46, miner by occupation. Compound fracture of frontal bone. Paraplegia, cystitis, incontinence of urine and feces, limbs wasted, improved for a time, so that he could stand with some assistance, chills and fever with spasms of the limbs and emaciation followed.	Operation performed 592 days after his admission. The cauda equina was found to be atrophied and soft. Hard inflammatory tissue filled the vertebral canal. Death on the day of the operation, which was partly expected.
No. 6. Operated on May 8, 1891. Thomas M., aged 19, laborer by occupation. Paraplegia; severe pain at 11th dorsal. The spine of the 11th dorsal indented, severe pain and spasms in posterior muscles of the thigh,	The spinous processes of the 9th, 10th, 11th and 12, and the laminæ of the 10th, 11th, and 12th were cut away; they were driven down, making compression upon the cord, especially the 11th. Pain and spasms soon subsided.

cystitis, constipation, had to use the catheter to relieve his bladder.	Sensation and motion gradually returning. Recovery except slight paralysis of posterior muscles of the thighs, with some ankle clonus. Cannot retain his urine long.	No. 12. Operated on Jan., 1894. Brom S., aged 24, mine laborer by occupation. Total paralysis of left leg and part of thigh. Right leg or thigh not so bad. Extreme ankle clonus, lacerated wounds of scalp, incontinence of urine and feces, cystitis. Priapism at times lasting from 6 to 12 hours. Has had violent attacks of orchitis. The extensor muscles are slightly improving.	Operated, 3 months after his admission, because of beginning gangrene of his toes on the left foot. This side being worse, it was evident that the pressure was on some of the nerves in the sacrum. It was found that there was compression on two of the nerves as they emerged from the sacrum. The compression was relieved. The gangrene soon disappeared. His limbs are atrophied, though he can move his legs. Under treatment for 819 days. He is able to walk with crutches.
No. 7. Operated on June 29, 1891. James C., aged 18, driver in the mines by occupation. Absolute motor and sensory paralysis from just below the anterior, superior spinous process in front and gluteal notch behind. Excruciating pain in the lumbar region extending into genitalia, slow, feeble pulse, labored respiration, shock continued for 5 days.	Operation the same as preceding cases. Membranes lacerated and cord almost separated. Operation performed 2 weeks after the injury. Pus had formed and was burrowing beneath the muscles and had entered the vertebral canal. Death in 35 days.		
No. 8. Operated on Nov. 30, 1891. Charles K., aged 37, miner by occupation. Paraplegia, symptoms similar to former case.	Lateral dislocation of 12th dorsal, cord crushed so that nothing but the membranes could be felt for nearly an inch. Tension taken off of the cord by cutting away the sides of the arches. Wound healed. Died in 565 days from exhaustion.	No. 13. Operated on March 22, 1893. George R., aged 23, miner by occupation. Total paralysis of lower part of trunk and limbs. Involuntary defecation and micturition. Severe pain, 8th dorsal spine very prominent, difficulty in breathing, severe shock, death imminent, operation delayed, gangrene in lumbar and sacral region, abscess in scrotum.	Some improvement in bed-sore, abscess healed, operation 6 weeks after reception of injury. 9th dorsal vertebra was fractured and driven in tightly compressing the cord. Wound healed and some improvement followed. Patient was taken to his home 5 weeks after the operation.
No. 9. Operated on May 8, 1892. Andrew C., aged 32, railroad laborer by occupation. Gun-shot wound of neck. High temperature. Respiration slow and labored. Delirium. Cyanosis of the face, neck and extending down over his chest.	Fracture of 5th or 6th cervical; cord and membranes lacerated. Inflammation of membranes and cord. The spines of the 5th and 6th, and a part of the arches were cut away, as little bone was removed as possible. Post mortem showed hemorrhages into brain and inflammation of the membranes. Died in 4 days.	No. 14. Operated on August 18, 1894. George Z., aged 26, a miner by occupation. On the day of his admission, January 12, 1894, the lower portion of his body and limbs were completely paralyzed. Fracture of forearm, compound fracture of second metacarpal, compound complicated fracture of last phalanx of index finger, with extensive lacerations of hand and face, and contusions of back. He was suffering from severe shock, and it seemed as though death would soon intervene. Pulse weak and rapid. Temperature from 100 to 104. In 4 days he began to rally and the case looked more hopeful. A large bed-sore soon appeared with extensive sloughing. No improvement seemed to follow for some 7 or 8 months. Then the bed-sore commenced to heal, but was soon followed by local gangrene of the skin of his feet and legs, cystitis and orchitis with abscess of left testicle.	The operation revealed the fact that the 11th and 12th dorsal vertebræ were fractured and that the cord and membranes were completely separated for about 2 inches. The ends of the cord were degenerated. His limbs were atrophied, abscess opened in the knee-joint with extensive gangrene of the skin. He was taken to his home and died in about 2 weeks. He was in the hospital 314 days.
No. 10. Operated on April 7, 1893. Andrew A., aged 25. Total paraplegia, lacerated wounds of hands, arm, head and leg. Shock, pupils dilated, rapid pulse.	Operated immediately, comminuted fracture of 10th dorsal, membranes punctured and cord lacerated. Died 3 days after his admission.		
No. 11. Operated on June 22, 1893. Carmin B., aged 47, mine laborer by occupation. Complete paraplegia from pelvis down. Labored breathing, pupils dilated, patient cyanotic, urine suppressed.	Operated at once. Fracture of the 3rd or 4th cervical vertebra, membranes and cord almost severed, considerable fluid escaped as soon as the skin was cut through. It was almost a compound fracture. Symptoms continued until death. Only a few ounces of urine were secreted in 4 days. Died in 4 days.		

COMMUNICATIONS.

ACETANILID VERSUS QUININE TO ABORT CHILLS AND FEVER; AND ACETANILID AS A DUSTING POWDER.*

BENJAMIN H. BRODNAX, M.D., BRODNAX, LA.

In 1890, I first used acetanilid in a case of catarrhal fever with convulsions, in an infant nine months old, with astonishing amelioration of all grave symptoms in fifteen minutes. My next trial of the drug was in intermittent fever in a family of three small children. The doses ranged from two to three grains, and when the time for the chills arrived the children were asleep and perspiring. I have employed the drug quite extensively, but it is especially in chills and fever that I desire to emphasize its great merit. My mode of using it is as follows:

If there is time before the chill I give from one and a half to two grains of calomel in quarter-grain doses a half hour apart. Then, whether the bowels have acted or not, I give, according to the age, from two to six grains of acetanilid twenty minutes or half an hour before the expected chill. Gentle perspiration, with sweet and natural sleep, usually promptly follow the administration of the drug, from which the patient wakens entirely relieved and ready to go about in half an hour.

When there is not time before the chill to administer the calomel it may be deferred until afterward; but the acetanilid may be given immediately before or during any stage of the chill or fever, with the happy result of promptly inducing sleep and gentle perspiration. Should the desired effect of the drug—viz., sleep and perspiration—not follow its administration within a half hour, a second dose of equal amount should be given.

The after-treatment consists of an acid tonic, viz.:

> Acidi. nitro. muriatici dil...f℥j
> Ferri sulphatis.....gr. lxxx.—M.
> This should stand for twenty four hours. S. Ten drops in water three or four times a day.

On Friday, October 19th, I was called to see a young man who had had "dumb" chills, with vomiting and severe gastric disturbances, for six days, the attack coming on daily at one o'clock and lasting until midnight. When I arrived, at seven o'clock in the evening, he was vomiting thick, glairy mucus, and was unable to retain anything on his stomach. I immediately administered hypodermatically one-quarter of a grain of morphine and gave six grains of acetanilid dry upon the tongue. He had one slight attack of vomiting soon after, but a little later fell into a sweet and a refreshing sleep, from which he did not waken until seven o'clock the next morning. As the next chill was expected at one o'clock he was ordered to take six grains of acetanilid twenty minutes before. No chill followed, and none have taken place since. The after-treatment with the "acid tonic" was pursued, as is always my custom.

I have now treated several hundred cases of chills with acetanilid, and without quinine, and report my success in the hope that others will be induced to give it a trial.

Acetanilid and boric acid, in equal parts, as a dusting powder, I have used extensively in ulcers, burns, etc. I find the powder especially serviceable in the excoriation of infants and fleshy people; with it I dust the funis of the newborn babe, while over the vulva of the mother I place a little cotton previously well dusted with the powder. Made into a paste with glycerin, I have used it in a vaginal tampon to allay uterine pain.

In the case of a female, sixty-one years of age, almost crazed with the itching from a pustular eruption that covered the lower part of the abdomen, vulva, and anus, the powder well dusted over the affected parts, after first moistening the parts with dilute carbolic acid, was followed by six hours of consecutive sleep. She was wakened by a return of the itching, and, rising, washed the parts and re-

* Read before the Philadelphia County Medical Society, February 13, 1895, by Dr. Oscar H. Allis.

applied the dilute carbolic acid and powder, with immediate return to sleep. A great improvement was observed the next day, and in a few days the parts were well. Previous to the application of the powder she had not slept well for several nights even with the aid of morphine.

Internally I have used it to correct a foul breath; also in dysentery and diarrhœa. When taken on the tongue and held in the mouth a few moments before swallowing, it has the effect of allaying the distressing thirst that accompanies fever.

AN INTERESTING CASE OF RAPID SPEECH DEVELOPMENT IN ADULT, FOLLOWING OPERATION FOR TONGUE-TIE.*

G. HUDSON MAKUEN, M.D., PHILADELPHIA.

The patient whom I shall show you this evening is nineteen years of age, a farmer by occupation, and up to within eleven months he has been utterly unable to use articulate speech in a manner which could be understood. He had been examined by local physicians and had been made to believe that his trouble was of central or cerebral origin, and that nothing could be done for him. The feeling that he was thus cut off from this chief means of communication with his fellows had completely disheartened him.

He had attended public school with other boys, and with the aid of his friends at home had managed to make some progress in arithmetic and to acquire a very slight theoretical knowledge of our language. He seemed to understand a little ordinary conversation, and learned easy lessons in history and geography by having them read to him. He would attempt to talk and recite in school, but his teachers had to guess, for the most part, at the meaning of his jargon. For myself I do not recall a single word that was at all intelligible. The first time he came to my office he could not make the conductor on the train understand the name of the station at which he lived, and after frequent attempts he was obliged to write it out, which he could do very imperfectly, for his spelling was almost as bad as his speech.

With a history of this kind, and being deprived of that greatest of all means of mental development—speech—you will be prepared to believe that he had acquired a reputation, even among those who knew him best, for listlessness and stupidity. Indeed, his aunt, with whom he came, had given up all hope of making anything of him; but the boy, discouraged as he was, seemed determined to make one more effort, and he was thoroughly in earnest.

Upon examination of his vocal and speech organs I found only a slight post-nasal catarrh and some little hypertrophy of the faucial tonsils. Of course, I thought immediately of the probability of his being tongue-tied, but his aunt assured me that there was nothing of the sort. I found, however, that he could protrude the tip of the tongue scarcely beyond the outer margin of the lips. The tip seemed a full inch or more too short, and, strange to say, the frænum did not appear to be a very decided factor in holding it down or back, for in his attempts to protrude the tongue the frænum was not greatly stretched. The trouble seemed to be a muscular one, and this I believe to be the case. The anterior fibres of the geniohyoglossus muscle were too short, and prevented not only the protrusion of the tongue, but any other free action of that member. He could elevate the back part of the tongue and make the hard G sound or the NG sound, but he could make no sound whatever which required the placing of the tip of the tongue to the roof of the mouth or the upper teeth. He made the K sound for T and hard G sound for D. As an example, he said "ik" for "it," and when I asked about his parents he said they were "gay"—meaning that they were dead. Furthermore, there seemed to be no method in his speech; it

*Read before the Philadelphia County Medical Society, February 18, 1895.

was a mere jumbling of inarticulate and unintelligible sounds, and the expression of his face was in perfect harmony with his speech—vacant, staring, meaningless.

The boy being somewhat delicate, and his friends being decidedly opposed to operative measures, and the cause of the trouble being doubtful, I decided to study the case carefully before giving an opinion or recommending methods of treatment. I gave him some vocal exercises for a few days and watched the results, after which I clipped the frænum of the tongue well back.

I then put him in the hands of a teacher, who gave him, under my direction, several hours' vocal drill each day for several months, during which time he made considerable improvement in sounds and words which did not require free action of the tip of the tongue. By this time I was convinced that the trouble was entirely a local one, and that the boy was of more than average intelligence and well worth developing. I then decided to divide the anterior fibres of the geniohyoglossus muscle, and thus try to give to the tongue the necessary freedom of action. His people would not give their consent to etherization, for they were skeptical as to favorable results from any measures whatever. The boy, however, was desperate, and would submit to anything which promised relief. We took the matter into our own hands, therefore, and with cocaine anesthesia I made an incision under the tongue of three-quarters of an inch in the anteroposterior direction and one and one-half inches from side to side. There was considerable bleeding, which was easily controlled, and, of course, there was also some pain.

He came to my office each morning for five days thereafter, and I broke up little adhesions which had formed and practiced slight lingual traction. On the morning of the sixth day he came in a great state of excitement, and with much pain, which he referred to the region of his tongue and throat. The tongue was greatly swollen, filling the entire mouth and protruding between the lips. He had a temperature of 103°. The larynx became involved to the extent of threatening suffocation, and I thought it would surely be necessary to open the trachea, which I made all preparations to do, but after succeeding in giving him a brisk purge the inflammation gradually subsided and the breathing became less labored. He was confined to bed for ten days, after which time he practiced frequent lingual traction and vocal exercises directed toward a free action of the tongue. His improvement from this time on has been most wonderful. Here we have a young man, nineteen years of age, who less than a year ago could not pronounce intelligibly more than three words of our language, could not buy a morning paper or tell you where he lived, and could not give his name to save his life. What he can do to day, with your permission, Mr. President, I shall try to demonstrate to you. I shall ask him to recite in your hearing Brutus' speech against Cæsar.

A New Antipyretic.

Tussol is the name given to a compound of amygdalic acid and antipyrine. Dr. Rehn of Frankfort-on-the-Main, has used the drug recently in quite a number of cases of whooping cough in children. He has found it useful in reducing the frequency of the paroxysms and mitigating their intensity, that its action is different from that of simple antipyrine, and that no untoward effects have been observed from its use. It is soluble in water, and as a corrigent raspberry syrup is better than milk. The minimum doses for children are as follows: Under one year of age, from three-quarters of a grain to a grain and a half, two or three times a day; from one to two years, a grain and a half three times a day; from two to four years, from three grains and three-quarters to six grains, three or four times a day; for older children, seven grains and a half, four times a day or more.

The Inheritance of Insanity.

Dr. G. Fielding Blandford, President of the Physiological Section of the British Medical Association, took as the subject of his opening address, "The Prevention of Insanity." One of the most important factors in the etiology of the disease, he said, is heredity. Sir Benjamin Ward Richardson has made the assertion that insanity is transmitted through the male line, but the speaker held that the reverse is the case, the taint passing through the female line rather than the male. He did not, however, insist so strongly on this point, holding that the safest rule was that no one, man or woman, who had had an attack of insanity should marry.

VARICELLA COMPLICATED WITH GANGRENE OF THE SCROTUM.*

CHARLES D. SPIVAK, M.D., PHILADELPHIA.

Jonathan Hutchinson was the first to draw the attention of the medical profession to a complication of varicella characterized by the development of gangrene of the skin and deeper tissues at the site of the eruption. Since his memorable article on "Gangrenous Eruption in Connection with Vaccination and Chickenpox" (*Med. Chir. Trans.* vol. lxv., p. 1), similar cases have been reported from England by Abercrombie (*Trans. Path. Soc. Lond.*, vol. xxxi., p. 333), Martin (*Brit. Med. Journ.*, 1881, vol. ii., p. 803), Howard (*Ibid.*, 1883, vol. i., p. 904), Jamieson (*Trans. Med. Soc. Edin.*, 1886-87, vol. vi.), Andrew (*Clinical Record*, 1890, vol. i., p. 63, and *Trans. Clin. Soc. Lond.*, vol. xxii., p. 79), Blowly (*Lancet*, London, 1885, vol. i., p. 987), Payne (*Trans. Path. Soc. Lond.*, vol xxxvi., p. 471), Crocker (*Med. Chir. Trans.*, vol. lxx., p. 397), and Stanifooth (*Med. Press and Circular*, London, 1890, vol. xlix., p. 37). The United States and Germany are represented in the literature on the subject by two authors each: the first by Woodward (*Pacific Med. and Surg. Journ.*, 1889, vol. xxxii., p. 197) and A. F. Büchler (*Amer. Journ. Med. Sci.*, 1889, vol. xcviii., p. 265, and the latter by Demme (*Wiener Med. Blätter*, 1892, vol. xv., p. 3) and Cassel (*Archive für Kinderkrankheiten*, 1894, vol. xvii., p. 371). Whether the children of other nationalities are exempt from this complication, or the cases have not been reported, I do not undertake to decide. So far as my researches go I could not find a single case in the French, Italian, Russian, or Spanish medical literature. The rarity of the complication in general, and the exceptional features of the case which came under my treatment in particular, justify me in reporting the same before you.

The patient was a boy of Russian parentage, aged two years, whose father and mother are healthy, with no scrofula or tuberculosis in family, and with five other children all well and healthy. Had had no serious illness previous to the attack of chickenpox. As I saw the case for the first time only on the eighth day of the disease I have to rely upon the data furnished by the parents, who proved to be tolerably good observers and quite reliable. On November 25, 1894, the appearance of the chickenpox was noticed for the first time; on the 26th the child became restless and had fever; on the 27th the fever increased, the child was delirious, and the scrotum became red and swollen. This state continued until the 30th, when the swelling extended to left inguinal region; a black spot, the size of a pin-head had appeared on the left side of the scrotum, and soon several others formed a circle around the original one and coalesced. On the following day another black spot appeared, a little further to the left on the scrotum, and "before one had time to look at it," as the parents expressed themselves, the process of deep ulceration and "eating up" commenced. On December 3d I saw the child for the first time. The child was well preserved and plump, as seen on the photograph and by its appearance now, and somewhat irritable. The penis, the scrotum, and the left inguinal region were very much swollen and tender. The left side of the scrotum was covered by blackish, muddy-looking crusts, and detritus covering about two-thirds of it and passing over the raphe to the right side. The smell was very offensive. The crusts and detritus were carefully removed and the tunica albuginea of the left testicle was exposed to the view, thus showing that the gangrenous process destroyed not alone the integument but also the dartos, the external cremasteric, and internal fascias, and the tunica vaginalis. There was a distinct areola around the ulcer. The existence of pus in the inguinal region was easily demonstrated by its fluctuation and also by the oozing from a very small spontaneous opening found about half an inch from the scrotum. The temperature was 101.6°, pulse 110. Pressure over the bubo gave pain, but the handling of the ulcer was almost painless. I washed the

* Read before the Philadelphia County Medical Society February 13, 1895.

parts with bichloride and applied the iodoform-gauze dressing and bandage. On the following day, when the bandage was removed, the ulcer was found to present a somewhat better appearance, but was still angry looking and covered with pus from the oozing aperture. The child was anesthetized by Dr. Rachel Skidelsky, and introducing the groove director through the opening I laid open the ingunial region throughout its length, as is seen on the photograph. I cleansed the wound thoroughly and packed it with iodoform-gauze. (At this juncture the photograph was taken, which shows the incision with the packing in it; the left testicle exposed and many spots of dried up vesicles all over the body.) The ulcer was dressed with bichloride gauze saturated in hydrogen dioxide, and applied a T-bandage. Of course the ulcer required a good deal of trimming of the dead tissues. I ordered two grains of quinine to be given in the evening and two grains in the morning. It was then that I noticed that three children in the family had varicella in different stages of development. There were no complications in the other cases.

On the following day the temperature fell to 99.2°; the child slept almost the whole night, the first time since it was taken sick; the ulcer and wound were clean and the gangrenous process checked. The local treatment was continued the same during the entire period of the regeneration of the scrotum, which took about thirty-five days. The repair is complete and admirable, as you can see on the child, leaving only a star shaped cicatrix. No internal treatment was needed after the third day.

Through the kindness of Dr. J. S. Billings, Deputy Surgeon-General U. S. Army, I was enabled to trace the literature on the subject antedating the report of Hutchinson. Besides the mention by Hutchinson of two casts in Guy's Hospital Museum, which were named varicella eschorotica, and the case of Stokes described in 1807 in his *Dublin and Physical Essays on Eruptive Diseases in Children*, which he named pemphigus gangrenosa, and which, according to Hutchinson are to be regarded as cases of varicella gangrenosa, the following cases were reported and minutely described by their respective authors as varicella complicated with gangrene. Dr. Humphrey Storer (*Boston Med. and Surg. Reporter*, 1828, vol. i., p. 212), Steinthal (*Analekten.*, 1843), Laewenhardt (*Rheinische Monat. für Prakt. Aerzt.*, 1850), Dr. Frederick J. Brown, of Rochester (*Brit. Med. Journ.*, 1863, vol., ii., p. 420), and Dela Harpe (*Bull. Soc. Med. de la Suiss Rom.*, 1869).

Treatment of Epilepsy.

According to the *American Medico-Surgical Bulletin*, Eulenburg recommends a combination of one part of ammonium bromide to two parts each of potassium and sodium bromides, to be given in a weak watery solution; the dose to be regulated by the number, character, intensity, duration and time of occurrence of the fits; also, the conditions presented in the interim, the average daily dose for an adult being from one to two drachms, but four to five drahms may be safely given if the patient be carefully watched, and to avoid stomach trouble it is preferable to administer the dose about half an hour after meals.

Intolerance may be overcome by beginning with small doses of bromide combined with arsenic and iron.

When a daily dose of the bromides sufficient to control the paroxysms has been determined, it should be rigidly adhered to throughout the treatment, and the bromides are, under all conditions, to be continued for three years after the last fit.

For Ringworm.

Iodine has been found to be one of the most effective agents for destroying the parasite upon which this disease depends. An excellent method of applying it is the following: Thoroughly cleanse the scalp with soap and water. Dry perfectly, then apply a solution of one part of pure iodine in thirty parts of flexible collodion. Renew the application each day for four days. At the end of fifteen days renew the collodion, wash the scalp first with soap and water, then, after thoroughly removing the soap, wash with a hot solution of bichloride of mercury, one twenty-five-hundredth. After allowing the bichloride solution to remain in contact with the scalp for half an hour, wash with pure water, dry, and apply vaseline or zinc ointment. If necessary, repeat the application.—*Mod. Med.*

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

ELECTRICITY IN UTERINE FIBROMAS.

Dr. Mally (*Annales de Gynecologie*, No. 10, 1894) reports on thirty-three cases of fibroma of the uterus which he has treated by electricity. In seven the symptoms wholly disappeared (menorrhagia); the results were less favorable in cases where the appendages had been injured during laparatomy; in one patient, who left off treatment, there was a salpingitis; in four cases he noticed an actual diminution of the size of the growth; in four there was no decrease in size, and in one a real increase. He describes two procedures for the application of electricity: a surgical and a medical application. The surgical, characterized by deep cauterization, he holds indicated in—

1. Fibromas that are increasing in size.
2. Fibromas with simultaneous disease of the appendages.
3. Fibromas that project into the cavity of the uterus and which will probably be easily enucleated.

Otherwise the usual measures (medical) are to be employed, with introduction of the positive and negative poles, with their well-known action.

GALVANIC IGNIPUNCTURE IN LUPUS TELANGIECTODES.

Dr. D. Majocchi (*Berliner Klinische Wochenschrift* No. 20, 1894) in a case of lupus teleangiectodes disseminatus of the lower extremities which was characterized by a great overdevelopment of the capillary vessels in the region of flat and slightly infiltrated plaques employed galvanic ignipuncture with very satisfactory results. Later in the disease these capillary ramifications enlarge so as to present a bluish and varicose appearance upon a red background.

TREATMENT OF PLANTAR AND PALMAR KERATODERMIA.

Dr. Brocq (*Journal Des Maladies Cutanées et Syphilitiques*, No. 11, 1894) calls attention to the obstinacy and proneness of this disease to recur. Internally, large doses of arsenic are of service. Locally, the indurated patches may be softened with prolonged baths, poultices, rubber gloves, compresses of hot water, covered with impermeable protective; then the epidermis is easily removed by a scraper or the nails. This treatment is then best followed by local application of black soap until all the epidermis is detached and only the thin subcorneous layer remains; then a glycerole of starch to which a-twentieth of salicylic and tartaric acids have been added is of value. After employing the black soap he also advises the use of the following formula:

Tartaric acid..... }	āā	1	0 grs xv
Salicylic acid..... }			
Carbolic acid.....		0	50 " vijss
Resorcine.....		1	50 " xxiiss
Lanoline.....		18	0 ʒiv, grs xxx
Vaseline.....		7	0 ʒj, ʒ4

ICTERUS AFTER THE USE OF MALE FERN AS A TAPE-WORM REMEDY.

Dr. E. Grawitz (*Berliner Kilnische Wochenschrift*, No. 52, 1894) warns against administering the extract of male fern-extractum filicis maris æthereum as a tænicide to those who are liable to liver affections, who are hard drinkers or have had syphilis, as this drug has a deleterious influence upon that organ, and may, in certain cases, lead to an interstitial hepatitis and which drug is possibly of significance in determining cirrhosis of the liver. Above all, he would not administer it at the same time with castor oil.

PRURITUS OF THE VULVA.

Dr. N. Guéneau de Mussy (*Spit.* No. 21, 1894) praises in the treatment of pruritus of the vulva, the following formula:

Glycerole of starch.....	20	0 ʒv
Bismuth subnitrate	1	0 grs. xv
Bromide potash	1	0 grs. xv
Extr. belladonna.....	0	25 grs. iv
Calomel	0	50 grs. viij

Apply locally.

* In charge of the translator, F. H. Pritchard, M.D.

TREATMENT OF CANCROID.

Dr. Brocq (*Journal Des Maladies Cutanees et Syphilitqiues*, No. 11, 1894) has observed the chlorate of potash and resorcine to be the remedies acting best in cancroids. In a diabetic male patient with granulating epithelioma of the prepuce he recommended local application of the finely powdered chlorate of potash and dressing with compresses dipped in:

Chlorate potash	50	0	ʒ jss
Resorcine	5	0	ʒ j¼
Distilled water	500	0	ʒ xv, ℥v

Instead of this the following salve he also recommends:

Resorcine	1	0	grs. xv
Chlorate potash	3	0	grs. xlv
Vaseline	20	0	ʒ v

GLYCERINE TO INDUCE UTERINE CONTRACTIONS

Dr. P. L. Ferrari (*Lo Sperimentale*, No. 36, 1894) after an exhaustive study of the question of the use of intra-uterine injections of glycerine to bring on uterine contractions, concludes as follows:

1. Glycerine injected into the uterine cavity to induce premature labor or abortion, is not reliable, in its action, neither as to the appearance of the pains, their intensity nor duration.

2. Glycerine is harmful and actually dangerous on account of the changes which it causes in the blood and the kidneys and it should be absolutely excluded in those cases where a renal lesion is either diagnosed or suspected.

3. Glycerine may be injurious to the child or even fatal.

INTESTINAL COLIC IN CHILDREN.

Dr. Ciro L. Urriola (*Rivista Clinica E Terapeutica*, No. 12, 1894) recommends highly the following mixture, in the colic of children:

Tr. Belladonna			gtts. xx–xl.
Destilled cinnamon water.	60	0	(ʒij).

A teaspoonful every hour until relief follows.

In treating the constipation which is the chief cause of the colic of these little patients he administers cod-liver oil in doses of three to five teaspoonfuls a day.

Dr. Escherich (*Ibidem*) in the treatment of chronic constipation accompanying chronic tuberculosis of the peritoneum or of the intestines in children, advises the use of the following formula:

Sulphate atropine		0	003.
Water	100	0	(ʒiij. ʒj).
Gum mixture	20	0	(ʒv).

To obtain the desired effect this preparation must be long continued. One may also at times administer a laxative. During the whole time that this mixture is given the pupils should be carefully watched.

SALVE FOR LUBRICATING SOUNDS.

Prof. Guyon (*Norsk Magazin for Lægevidenskaben*, No. 12, 1894) employs in his clinic, the following salve as a lubricant for urethral sounds:

Soap	50	0	(ʒjss).
Glycerine			
Water ää	25	0	(ʒvj).
Bichloride mercury	0	02	(gr. ⅓).

This salve is aseptic, does not irritate the urethra and renders catheterization easy.

CRÉDÉ'S PROCEDURE IN THE PLACENTAL STAGE OF LABOR.

Dr. Pelzer (*Hospitals Tidende*, No. 50, 1894) has collected one thousand cases treated by Crede's method a half hour after birth of the child and compares them with five hundred from the same institution treated by Ahlfeld's method—the placenta removed after two hours by a light pressure upon the uterus—finding that severe hemorrhages are far more frequent, puerpural febrile complications of the same percentage and a slightly less retention of membranes with the expectant treatment.

TRAUMATIC PULSATING EXOPHTHALMOS.

Dr. Hansen (*Muenchener Medicinische Wochenscrift*, No. 51, 1894) observed a woman who after being run over by a wagon developed signs of a fracture of the base of the skull and pronounced and pulsating exophthalmos of the right eye which, on auscultation, yeilded a blowing sound. This form of exophthalmos is, as a rule, the consequence of an arteriovenous aneurism of the cranial cavity from rupture of the internal carotid into the cavernous sinus. He intends to treat it by long continued compression of the carotid or if this fail, by ligation of that artery.

A NEW WAY OF ADMINISTERING COD-LIVER OIL.

Dr. Dietrich (*Revue Internationale de Medicine et de Chirurgie Pratiques,* No. 19, 1894) has succeeded in masking the disagreeable taste of cod-liver oil by the following formula:

Cod-liver oil	1000	o	℥xxxj ℥ij
Essence lemon	5	o	℥j ¼
Essence Clove	2	o	grs xxx
Essense peppermint	1	o	" xv
Vanilline	0	10	" jss
Cumarine	0	01	" 1 1-6

The cumarine and the vanilline are dissolved in the essential oils which are slightly warmed and this solution is mixed with the oil.

SALICYLATE OF SODA BY THE RECTUM.

Prof. V. Ziemssen (*Wiener Medizinische Presse,* No. 52, 1894) in those cases where there is a peculiar idiosyncrasy with regard to the salicylates advises giving it in clysters. Absorption takes place from the rectum nearly as promptly and with as good therapeutic results as though it were given by the mouth. From two to three grams (grs. xxx—xlv) at a dose are dissolved in fifteen to twenty grams (℥ iv—v) of warm water and this injected; it may be repeated if necessary. The disagreeable symptoms of an overdose, as ringing in the ears and sweating also are observed with this method of administration, but the nausea and disgusting aftertaste are avoided. He can also recommend giving other disagreeably tasting remedies by the rectum as, for example, the different preparations of squills. As to the percutaneous use of the salicylates by means of a salve applied to the painful joints he also thinks quite favorably of it and has obtained with it good results. Absorption is accelerated by addition of turpentine to the formula, though it is not absolutely necessary for it will take place with the pure acid alone. He uses the following formula:

Salicylic acid Oil turpentine	āā 10	o	℥ijss
Lanoline	30	o	℥j
Vaseline	50	o	℥jss

TREATMENT OF ACUTE TONSILITIS.

Dr. Miles (*Rivista Clinica E. Terapeutica,* No. 12, 1894) advises in acute tonsillitis the following treatment:

Essence Eucalyptus	1	o	gtts xv
Spirits Camphor	5	o	℥j ¼
Tr Guaiac	15	o	℥iv
Glycerine	10	o	℥ijss

Every hour or two pour ten drops of this mixture upon a lump of sugar which is allowed to melt in the mouth.

When the fever is intense the following powders are of service:

Acetanilid Phenacetine	āā 1.25	(grs xviij)

Sufficient for six powders. One every four to six hours.

At the same time one may apply externally to the neck the following:

Tr. Lobelia Tr. aconite root	āā 8	o	℥ij
Chloroform	10	o	℥ijss
Essence Turpentine	12	o	℥ij

Dr. L. Emmett Holt, in *Archives of Pediatrics,* summarizes the treatment of diphtheria as follows:

1. Germicidal treatment, preferable by the use of a strong hydrochloric acid, used early to be effectual; especially valuable in cases beginning on the tonsils.
2. Local cleanliness by the use of a weak antiseptic solution in the pharynx.
3. Nasal syringing with the same solutions in every case where there is nasal discharge.
4. Alcoholic stimulants begun as soon as the first systemic effects of the poison are seen, and in very severe cases pushed to the point of tolerance.
5. Calomel fumigations as soon as laryngeal symptoms appear.
6. Intubation in laryngeal cases not relieved by fumigations.

Ipecacuanha as a Uterine Stimulant.

Drs. Stillmark and Utt, of Russia, after a series of experiments upon parturient women, have demonstrated that ipecacuanha is a valuable stimulant to the contractions of sluggish uterus during labor. They administered three successive doses of ten drops each of wine of ipecac at intervals of ten minutes. In from twenty to thirty minutes the contractions of the uterus became of normal strength and duration. In but one case were the contractions of the uterus noticed to be spasmodic in character, and the observers conclude that ipecacuhanha possess much less tendency to cause tetantus of the uterus than ergot.—*La Semaine Medicale.*
